## Preface

At its core, the study of animal cognition and behavior is interdisciplinary, drawing on the work of biologists, zoologists, psychologists, and anthropologists, to name a few key fields. With these diverse perspectives, a certain lack of convergence of definitions of key constructs is inevitable. This is especially true with the study of animal cognition because it necessitates the inference of underlying processes that cannot be directly observed or experienced. It is therefore essential to carefully operationalize those underlying constructs from a swath of behaviors that can be directly observed. This volume covers the behaviors of species that differ as immensely as, for example, the honeybee from the beluga whale. Thus, behaviors that serve similar underlying functions and motivations may appear vastly different across species. Established researchers and novice investigators alike might struggle to reconcile and synthesize the vast research on a rapidly expanding array of study species. It is the goal of this *Encyclopedia of Animal Cognition and Behavior* to bring some clarity to the ever-changing views and topics explored by the many researchers that contribute to knowledge of animal behavior and to celebrate the similarities and differences among species afforded by evolutionary processes.

We hope that interested readers, as both novel entrants into the research community and more senior investigators looking for concise reviews of the latest consensus on a topic, will find this volume to be a valuable resource. This *Encyclopedia of Animal Cognition and Behavior* is the culmination of an intense and laborious undertaking that relied upon the expertise and talents of International contributors, section editors, and editorial/production staff at Springer for whom we are sincerely grateful.

## About the Editors

**Jennifer Vonk** received her Ph.D. in comparative psychology from York University, Canada, in 2002 and previously held a faculty position at the University of Southern Mississippi before joining Oakland University in 2011 where she is a professor of psychology. She examines the mechanisms underlying cognition and behavior in diverse species (including amphibians, reptiles, birds, mammals, human children and adults) with the goal of better understanding the evolutionary factors giving rise to cognitive capacities. She also conducts research that contributes to improving the welfare of captive species. She has published over 100 empirical papers, book chapters, commentaries, and edited volumes and has held several editorial positions including co-editor-in-chief for *Animal Behavior and Cognition* and section editor for *PeerJ*. She is a fellow of the Society for Behavioral Neuroscience and Comparative Psychology/Division 6 of the American Psychological Association.

**Todd K. Shackelford** received his Ph.D. in evolutionary psychology in 1997 from the University of Texas at Austin. Since 2010, he is professor and chair of the Department of Psychology at Oakland University (<http://www.oakland.edu/psychology>) in Rochester, Michigan, where he is co-director of the Evolutionary Psychology Lab ([www.ToddKShackelford.com](http://www.ToddKShackelford.com)). In 2016, he was appointed Distinguished Professor by the Oakland University Board of Trustees. He led the founding of new Ph.D. and M.S. programs (<http://www.oakland.edu/psychology/grad/>), which launched in 2012. Shackelford has published around

300 journal articles and his work has been cited over 27,000 times. Much of Shackelford's research addresses sexual conflict between men and women, with a special focus on men's physical, emotional, and sexual violence against their intimate partners. Since 2006, Shackelford has served as editor of the journal *Evolutionary Psychology* ([www.epjournal.net](http://www.epjournal.net)) and in 2014 founded the journal *Evolutionary Psychological Science* (<http://www.springer.com/psychology/personality+%26+social+psychology/journal/40806>) as editor-in-chief. Shackelford is an elected fellow of the Association for Psychological Science and the American Psychological Association.

## Section Editors

**Emily Boeving** Florida International University, Miami, FL, USA

**Joseph Boomer** Missouri Southern State University, Joplin, MO, USA

**Dawson Clary** University of Manitoba, Winnipeg, MB, Canada

**Zanna Clay** Department of Psychology, Durham University, Durham, UK

**Shannon M. Digweed** Departments of Psychology and Biological Sciences, MacEwan University, Edmonton, AB, Canada

**Constance Dubuc** University of Cambridge, Cambridge, UK

**Valerie Dufour** Social and Cognitive Ethology team, UMR7247, CNRS-IFCE-INRAE, University of Tours, Tours, France

**Sarah Dunphy-Lelii** Associate Professor (and Department Chair) of Psychology, Bard College, Bard College, Annandale, NY, USA

**Alexis Garland** Ruhr University, Bochum, Germany

**Marieke Cassia Gartner** Zoo Atlanta, Atlanta, GA, USA

**Akash Gautam** Centre for Neural and Cognitive Sciences, School of Medical Sciences, University of Hyderabad, Hyderabad, Telangana, India

**Lauren Guillette** University of Alberta, Edmonton, Canada

**David Hanbury** Associate Professor of Psychology, Averett University, Danville, VA, USA

**Lauren Highfill** Psychology and Animal Studies, Eckerd College, St. Petersburg, FL, USA

**Khalil Iskarous** Department of Linguistics, University of Southern California, Los Angeles, CA, USA

**Ivo Jacobs** Department of Cognitive Science, Lund University, Lund, Sweden

**Stephanie E. Jett** Georgia College and State University, Milledgeville, GA, USA

**Mark A. Krause** Department of Psychology, Southern Oregon University, Ashland, OR, USA

**Kenneth Leising** Texas Christian University, Forth Worth, USA

**Caroline Leuchtenberger** Federal Institute Farroupilha, Panambi, RS, Brazil

**Suzanne MacDonald** Department of Psychology, York University, Toronto, ON, USA

**Peggy Mason** University of Chicago, Chicago, USA

**Emily Patterson-Kane** Animal Welfare Division, American Veterinary Medical Association (AVMA), Schaumburg, IL, USA

**Annika Paukner** Nottingham Trent University, Department of Psychology, Nottingham, UK

**Oskar Pineno** Psychology Department, Hofstra University, Hempstead, NY, USA

**Mystra M. Samuelson** Animal Behavior Core, Department of Comparative Medicine, The University of Nebraska Medical Center, Omaha, NE, USA

**Cristina Díaz Clark** Institute for Marine Mammal Studies, Gulfport, MS, USA

**Hannah Clark** School of Psychology, University of Sussex, East Sussex, UK

**William James Clark** Department of Psychology, University of Otago, Dunedin, New Zealand

**Zanna Clay** Department of Psychology, Durham University, Durham, UK

**Nicola S. Clayton** Comparative Cognition Laboratory, Department of Psychology, University of Cambridge, Cambridge, UK

**Lauren Cleland** Department of Psychology, Texas Christian University, Fort Worth, TX, USA

**Jennifer Colbourne** York University, Toronto, ON, Canada

**Gemma L. Cole** School of Life and Environmental Sciences, Centre for Integrative Ecology, Deakin University, Waurn Ponds, VIC, Australia

**Cristianna Colella** Department of Biology, Queens College, City University of New York, Flushing, NY, USA

**Maura Collins** Department of Speech-Language-Hearing Sciences, Hofstra University, Hempstead, NY, USA

**Michael Colombo** Department of Psychology, University of Otago, Dunedin, New Zealand

**Ruth M. Colwill** Brown University, Providence, RI, USA

**Jenna V. Congdon** Department of Psychology, University of Alberta, Edmonton, AB, Canada

**John P. Connell** University of Tennessee, Knoxville, TN, USA

**Shannon E. Conrad** Department of Psychology, Texas Christian University, Fort Worth, TX, USA

**Nicole Copeland** Texas A&M College of Veterinary Medicine and Biomedical Sciences, College Station, TX, USA

**Daniela Corbetta** University of Tennessee, Knoxville, TN, USA

**Randy Corpuz** Department of Psychology, Boston, MA, USA

**Miranda Nicole Cosman** University of Michigan, Ann Arbor, MI, USA

**Joao H. C. Costa** Dairy Science Program, Department of Animal and Food Sciences, University of Kentucky, Lexington, KY, USA

**Austin Coulter** Department of Zoology and Physiology, University of Wyoming, Laramie, WY, USA

**G rard Coureaud** Centre de Recherche en Neurosciences de Lyon (Lyon Neuroscience Research Center) INSERM U1028, CNRS UMR 5292, Universit  Claude Bernard Lyon, Lyon, France

**Rita Covas** Percy FitzPatrick Institute, DST-NRF Centre of Excellence, University of Cape Town, Cape Town, South Africa

CIBIO, Research Centre in Biodiversity and Genetic Resources, Campus Agr rio de Vair o, Vair o, Portugal

Biology Department, Science Faculty, University of Porto, Porto, Portugal

**Bruno Cozzi** Department of Comparative Biomedicine and Food Science, University of Padova, Legnaro, PD, Italy

**Carmen M. Cromer** North Carolina State University, Raleigh, NC, USA

**Adam L. Cronin** Tokyo Metropolitan University, Tokyo, Japan

**Neil Crooks** School of Pharmacy and Biomolecular Sciences, University of Brighton, Brighton, UK

**Fiona R. Cross** School of Biological Sciences, University of Canterbury, Christchurch, New Zealand

International Centre of Insect Physiology and Ecology, Mbita Point, Kenya

**Angela Crumer** Kansas State University, Manhattan, KS, USA

**Maria Santa Cruz** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Jonathon D. Crystal** Department of Psychological and Brain Sciences, Indiana University, Bloomington, IN, USA

**Laura Cuaya** Universidad Nacional Autónoma de México, Queretaro, Mexico

**Carmelo P. Cubillas** Universidad a Distancia de Madrid, Madrid, Spain  
Universidad Autónoma de Madrid, Madrid, Spain

**Lorena Xolalpa Cueva** Instituto de Neurobiología, Universidad Nacional Autónoma de México, Querétaro, México

**Kathleen E. Cullen** Department of Physiology, McGill University, Montreal, QC, Canada

Biomedical Engineering, The Johns Hopkins University, Baltimore, Maryland, USA

**Evan T. Curtis** Booth University College, Winnipeg, MB, Canada

**Rogério G. T. da Cunha** Universidade Federal de Alenas, Alenas, MG, Brazil

**Hadi Dahhan** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Meghana Damaraju** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Jordan Danflous** Kentucky Wesleyan College, Owensboro, KY, USA

**Anne Sophie Darmaillacq** Université de Caen Normandie, Caen, France  
UMR 6552 CNRS, Université de Rennes 1, Ethos, laboratoire d'éthologie animale et humaine, Rennes, France

**Dola Das** Cleveland Clinic, Cleveland, OH, USA

**Megha Das** Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Sanjay Das** National Institute of Mental Health and Neurosciences, Bangalore, India

**Anisha David** Fernhill Gardens Apartment, HSR Layout, Bengaluru, India

**Gabrielle L. Davidson** Biological, Earth and Environmental Sciences, University College Cork, Cork, Ireland

**J. Quentin Davis** Augusta University, Augusta, GA, USA

**Randall Davis** Texas A&M University, 200 Seawolf Parkway, OCSB, Galveston, TX, USA

**Sarah Davis** University of St Andrews, St Andrews, Scotland

**Ellen M. Dawley** Ursinus College, Collegeville, PA, USA

**Michael R. W. Dawson** Department of Psychology, University of Alberta, Edmonton, AB, Canada

**Casey C. Day** Purdue University, West Lafayette, IN, USA

**Florent Déroît** Département Homme and Environnement, UMR7194, Muséum national d'Histoire naturelle, CNRS, Paris, France

**Hendrik de Buhr** ETH Zurich, Zurich, Switzerland

**Eros Moreira de Carvalho** Department of Philosophy, Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil

**Amber J. de Vere** Department of Psychology, University of Southern Mississippi, Hattiesburg, MS, USA

**Andrew Deane** Department of Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA

**Mariana de-Carvalho** Laboratório de Comportamento Animal, Departamento de Zoologia, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, Brazil

**Alex R. DeCasien** New York University, New York, NY, USA  
New York Consortium in Evolutionary Primatology (NYCEP), New York, NY, USA

**François-Xavier Dechaume-Moncharmont** Evolutionary Ecology Group, Université de Bourgogne Franche-Comté, UMR CNRS 6282 Biogéosciences, Dijon, France

**Cyro de Luna-Dias** Laboratório de Anfíbios e Répteis, Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Allegra DePasquale** Department of Anthropology, Hunter College of the City University of New York, New York, NY, USA

**Ana de Paz** Universidad Nacional de Educación a Distancia (UNED), Madrid, Spain

**Francisco Edvaldo de Oliveira Terceiro** Department of Physiology and Behavior, Universidade Federal do Rio Grande do Norte, Natal, Rio Grande do Norte, Brazil

Department of Anthropology, University of Zurich, Zurich, Switzerland

**Yasmim B. B. de Oliveira** Laboratório de Anatomia Comparativa de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, DF, Brazil

**Alex Pires de Oliveira Nuñer** Laboratory of Biology and Freshwater Fish Culture, Federal University of Santa Catarina, Florianópolis, Brazil

**Fred Victor de Oliveira** Laboratory of Mammal Evolution, Department of Zoology, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

**Marc H. E. de Lussanet** Department of Movement Science, University of Münster, Münster, Germany

Otto Creutzfeldt Center for Cognitive and Behavioral Neuroscience (OCC), Münster, Germany

**Adam Derenne** University of North Dakota, Grand Forks, ND, USA

**Vishwajit Ravindra Deshmukh** Department of Anatomy, All India Institute of Medical Sciences, Nagpur, Maharashtra, India

**Amanda M. Dettmer** Laboratory of Comparative Ethology, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, USA

**Philippe De Deurwaerdère** Université de Bordeaux, Bordeaux, France  
Centre National de la Recherche Scientifique UMR 5287, Bordeaux, France

**Bharati Dev** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Susmita Dey** Department of Zoology, School of Life Sciences, Royal Global University, Guwahati, Assam, India

**Meghna Singh Dhaka** IMS Engineering College, Ghaziabad, Uttar Pradesh, India

**Ruby Dhar** Biochemistry, All India Institute of Medical Sciences, New Delhi, India

**Pooja Dhiman** Jawaharlal Institute of Postgraduate Medical Education and Research (JIPMER), Puducherry, India

**Francisca Díaz** Universidad de Chile, Santiago, Chile

**Joseph F. Di Liberto** University of California, San Diego, CA, USA

**Luan Dias Lima** Departamento de Zoologia, Programa de Pós-Graduação em Biologia Animal, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil

**Thomas DiBlasi** Hofstra University, Hempstead, NY, USA

**Ludovic Dickel** Université de Caen Normandie, Caen, France

UMR 6552 CNRS, Université de Rennes 1, Ethos, laboratoire d'éthologie animale et humaine, Rennes, France

**Nancy Digdon** Grant MacEwan University, Edmonton, AB, Canada

**Shannon M. Digweed** Departments of Psychology and Biological Sciences, MacEwan University, Edmonton, AB, Canada

**Abigail DiMercurio** University of Tennessee, Knoxville, TN, USA

**M. Diravyaseelan** Department of Biochemistry, All India Institute of Medical Sciences, New Delhi, India

**Anne Caruliny do Monte Lima** Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Ednei B. dos Santos** GIGA – Neurosciences, University of Liege, Liège, Belgium

**Burak Doğruyol** Psychology Department, Altınbaş University, İstanbul, Turkey

**F. Stephen Dobson** Department of Biological Sciences, Auburn University, Auburn, AL, USA

**Arnrow Domingo** Hofstra University, Hempstead, NY, USA  
San Francisco State University, San Francisco, CA, USA

**Giuseppe Donati** Nocturnal Primate Research Group, Department of Social Sciences, Oxford Brookes University, Oxford, UK

**James C. Dooley** Department of Psychological and Brain Sciences, University of Iowa, Iowa City, IA, USA

**Ednei Barros dos Santos** University of Lethbridge, Lethbridge, AB, Canada

**Liam R. Dougherty** School of Biological Sciences, Centre for Evolutionary Biology, University of Western Australia, Crawley, WA, Australia

**Noreen Doyle** University of Arizona Egyptian Expedition, Tucson, AZ, USA

**Patrick Drumm** Arts and Sciences Division, Ohio University Lancaster, Lancaster, OH, USA

**P. Dubey** Department of Zoology, Banaras Hindu University, Varanasi, India

**Abhishek Dubey** Department of Biochemistry, Maulana Azad Medical College, New Delhi, India

**Pragya Dubey** Department of Zoology, Banaras Hindu University, Varanasi, India

**Julie Duboscq** Kyoto University Primate Research Institute, Inuyama, Japan

**Kathleen M. Dudzinski** Dolphin Communication Project, Port Saint Lucie, FL, USA

**Nicole Duffee** Education and Scientific Affairs, American Association for Laboratory Animal Science, Memphis, TN, USA

**Jen Duffy** Jane Goodall's Roots and Shoots Global Committee, The Jane Goodall Institute Global, London, UK

Roots and Shoots, The Jane Goodall Institute of Canada, Toronto, Canada

**Leandro Dumas** Laboratório de Entomologia, Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**Aimee S. Dunlap** Department of Biology, University of Missouri – Saint Louis, Saint Louis, MO, USA

**Marc Dupuis-Désormeaux** York University, Toronto, ON, Canada

**Juan F. Duque** Department of Psychology, University of Nebraska-Lincoln, Lincoln, NE, USA

**Shantanu Durgvanshi** Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Kate L. Durrant** School of Life Sciences, The University of Nottingham, Nottingham, UK

**Dominic M. Dwyer** School of Psychology, Cardiff University, Cardiff, UK

**Katherine H. Dyer** Department of Psychological Sciences, Kent State University, Kent, OH, USA

**Taryn Eaton** Oakland University, Rochester, MI, USA

**Shannon E. Eaton** University of Kentucky, Lexington, KY, USA

**George Economou** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Lavinia Eddy** Dolphin Biology and Conservation, Cordenons, PN, Italy

**Andrew J. Edelman** Department of Biology, University of West Georgia, Carrollton, GA, USA

**Jared Edge** Oakland University, Rochester, MI, USA

**Benjamin R. Eisenreich** University of Rochester, Rochester, NY, USA

**Nathan J. Emery** Queen Mary University of London, London, UK

**Anne L. Engh** Department of Biology, Kalamazoo College, Kalamazoo, MI, USA

**Amanda J. Epping** Ape Cognition and Conservation Initiative, Des Moines, IA, USA

**Timothy M. Eppley** Institute for Conservation Research, San Diego Zoo Global, San Diego, CA, USA

**Metin I. Eren** Department of Anthropology, Kent State University, Kent, OH, USA

**Martha E. Escobar** Department of Psychology, Division of Life Sciences, Oakland University, Rochester, MI, USA

**Holli C. Eskelinen** Dolphins Plus, Inc., Key Largo, Florida, USA

**Danilo Eugênio de França Laurindo Flôres** Universidade de São Paulo, São Paulo, SP, Brazil

**Kelly M. Evans** Doctor of Veterinary Medicine, Orlando, FL, USA

**Kristine O. Evans** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Linda Evans** Macquarie University, Sydney, NSW, Australia

**Naïla Even** Institut National Polytechnique, Ecole Nationale Supérieure d'Ingénieur en Art Chimique et Technologique (ENSIACET), Toulouse, France

**Joël Fagot** Aix-marseille University, CNRS, and Brain and Language Research Institute, Marseille, France

**Muneeb A. Faiq** Dr. Rajendra Prasad Centre for Ophthalmic Sciences, All India Institute of Medical Sciences (AIIMS), New Delhi, India

Neuroimaging and Visual Science Laboratory, Langone Medical Centre, New York University School of Medicine, New York, NY, USA

**Fereshteh Farajdokht** Neurosciences Research Center (NSRC), Tabriz University of Medical Sciences, Tabriz, Iran

**Kate Farmer** School of Psychology and Neuroscience, St Andrews University, Scotland, UK

**Mark J. Farnworth** School of Animal, Rural and Environmental Sciences, Nottingham Trent University, Southwell, Nottinghamshire, UK

**Patrizia Fattori** Department of Pharmacy and Biotechnology, University of Bologna, Bologna, Italy

**Livio Favaro** Department of Life Sciences and Systems Biology, University of Turin, Turin, Italy

**L. M. Fedigan** Department of Anthropology and Archaeology, University of Calgary, Calgary, AB, Canada

**Pawel Fedurek** Department of Primatology, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

**Sara B. Félix** Department of Education and Psychology, University of Aveiro, Aveiro, Portugal

**Jane C. Fenelon** University of Melbourne, Parkville, VIC, Australia

**L. A. Ferreira** Laboratório de Anatomia Comparada de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, DF, Brazil

**Larissa Ferreira-Cunha** Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Brandon Ferrell** College of Veterinary Medicine, Mississippi State University, Mississippi State, MS, USA

**Aurelio José Figueredo** University of Arizona, Tucson, AZ, USA

**Shannon Finerty** Kentucky Wesleyan College, Owensboro, KY, USA

**Renée Claire Firman** Centre for Evolutionary Biology, School of Biological Sciences (M092), The University of Western Australia, Crawley, WA, Australia

**Stefan Fischer** Mammalian Behaviour and Evolution Group, Institute of Integrative Biology, University of Liverpool, Leahurst Campus, Neston, UK

**Sylvain Fiset** Université de Moncton, Campus d'Edmundston, Edmundston, NB, Canada

**Carey Fitzgerald** Oregon Institute of Technology, Klamath Falls, OR, USA

**Erin M. Fitzpatrick-Wacker** Veterinary, TLC Animal Hospital, Houston, TX, USA

**Elizabeth A. Flaherty** Department of Forestry and Natural Resources, Purdue University, West Lafayette, IN, USA

**Molly Flessert** Georgia State University, Atlanta, GA, USA

**Cathleen Fleury** Western University, London, ON, Canada

**Hakima Flici** Centre for Chromosome Biology (CCB), School of Natural Sciences, National University of Ireland Galway, Galway, Ireland  
Regenerative Medicine Institute (REMEDI), National University of Ireland Galway, Galway, Ireland

**Jessie Fly** Eckerd College, Saint Petersburg, FL, USA

**Preston Foerder** Chattanooga, TN, USA

**Laurel Fogarty** University College London, London, UK

**Manuella Folly** Setor de Herpetologia, Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**Enrique Font** Instituto Cavanilles de Biodiversidad y Biología Evolutiva, University of Valencia, Paterna (Valencia), Spain

**Jennifer R. Foote** Department of Biology, Algoma University, Sault Ste. Marie, ON, Canada

**Jennifer K. Fortin-Noreus** Grizzly Bear Recovery Program, U.S. Fish and Wildlife Service, Missoula, MT, USA

**Elizabeth A. Forys** Eckerd College, St. Petersburg, FL, USA

**Quentin Fouche** CHU Lille, EA 7367 – UTML – Unité de Taphonomie Médico-Légale, Univ. Lille, Lille, France

**Stephen B. Fountain** Department of Psychological Sciences and Brain Health Research Institute, Kent State University, Kent, OH, USA

**Marlen Fröhlich** Anthropological Institute and Museum, University of Zurich, Zurich, Switzerland

**Dorothy Munkenbeck Frigaszy** Department of Psychology, University of Georgia, Athens, GA, Georgia

**Elisabeth L. Frankini** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Natalie S. Fraser** The University of Queensland, Gatton, QLD, Australia

**Cody A. Freas** Department of Biological Sciences, Macquarie University, Sydney, NSW, Australia

**Marianne Sarah Freeman** Royal Zoological Society of Scotland, Edinburgh, UK

**Kristin A. French** Georgia State University, Atlanta, Georgia, USA

**Erin E. Frick** Department of Psychology, University of Southern Mississippi, Hattiesburg, MS, USA

**Juliane Friedrich** The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Midlothian, UK

**Joachim G. Frommen** Department of Behavioural Ecology, Institute of Ecology and Evolution, University of Bern, Hinterkappelen, Switzerland

**G. Thomas Frost** Quincy University, Quincy, IL, USA

**Brett M. Frye** Department of Biological Sciences, Clemson University, Clemson, SC, USA

**Esmeralda Fuentes-Verdugo** Universidad Nacional de Educación a Distancia (UNED), Madrid, Spain

**Andrew Goldklank Fulmer** Lehman College, City University of New York, Bronx, NY, USA

**Jake A. Funkhouser** Central Washington University, Ellensburg, WA, USA

**Márta Gácsi** MTA-ELTE Comparative Ethology Research Group, Budapest, Hungary

**Casey Gähns** School of Biological Sciences, Illinois State University, Normal, IL, USA

**Peter Gagliano** Department of Electrical and Computer Engineering, New York Institute of Technology, Old Westbury, NY, USA

**Christina L. Gagné** University of Alberta, Edmonton, AB, Canada

**Elizabeth M. Gallagher** University College London, London, UK

**Claudio Galletti** Department of Pharmacy and Biotechnology, University of Bologna, Bologna, Italy

**Gordon G. Gallup** State University of New York at Albany, Albany, NY, USA

**Michela Gamberini** Department of Pharmacy and Biotechnology, University of Bologna, Bologna, Italy

**Vishwa Gandhi** Radiation and Photo Chemistry Division, Bhabha Atomic Research Centre, Mumbai, India

**Kostas Ganias** Aristotle University of Thessaloniki, Thessaloniki, Greece

**Ignacio Martínez García** Instituto de Neurobiología, Universidad Nacional Autónoma de México, Querétaro, México

**Óscar García-Leal** Centro de Estudios e Investigaciones en Comportamiento, University of Guadalajara, Guadalajara, Jalisco, Mexico

**Francisco Garcia-Gonzalez** Doñana Biological Station, Spanish Research Council (CSIC), Sevilla, Spain

Centre for Evolutionary Biology, School of Biological Sciences, The University of Western Australia, Crawley, WA, Australia

**Pinky Garg** Biochemistry, North Delhi Municipal Corporation Medical College, New Delhi, India

**Rajeev Garg** Paras Hospital, Panchkula, India

**Marieke Cassia Gartner** Zoo Atlanta, Atlanta, GA, USA

**Pankaj Gaur** The Loop Immuno-Oncology Laboratory, Lombardi Comprehensive Cancer Center, Georgetown University Medical Center, Washington, DC, USA

**Akash Gautam** Centre for Neural and Cognitive Sciences, School of Medical Sciences, University of Hyderabad, Hyderabad, Telangana, India

**Avinita Gautam** DST-CIMS, Banaras Hindu University, Varanasi, India

**Karuna Gautam** Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

**Pallavi Gautam** Centre of Advanced Study in Botany, Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

**Jamie Gehring** Allen Institute for Cell Science, Seattle, WA, USA

**Emel Gençer** Aziz Sancar Institute of Experimental Medicine, Department of Neuroscience, Istanbul University, Istanbul, Turkey

Süleyman Demirel University, Isparta, Turkey

**Rocco J. Gennaro** University of Southern Indiana, Evansville, IN, USA

**Peter Gerhardstein** Binghamton University, Binghamton, NY, USA

**David V. Gesicki** Department of Biological Sciences, Bowling Green State University, Bowling Green, OH, USA

**Paushali Ghosh** School of Biotechnology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Sanjib K. Ghosh** Department of Anatomy, All India Institute of Medical Sciences (AIIMS), Patna, India

**Shampa Ghosh** Endocrinology and Metabolism Division, National Institute of Nutrition (NIN), ICMR, Tarnaka, Hyderabad, India

**Dan E. Gibbons** Department of Anatomy, New York Institute of Technology, Old Westbury, NY, USA

**Carlos Eduardo Tadeo Gijón** Instituto de Neurobiología, Universidad Nacional Autónoma de México, Querétaro, México

**James Giordano** Departments of Neurology and Biochemistry, Georgetown University Medical Center, Washington, DC, USA

**Prerna Giri** Cytogenetics Laboratory, Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Ewen Glass** Lincoln School of Film and Media, University of Lincoln, Lincoln, UK

**Quincy M. Goeke** The Institute for Marine Mammal Studies, Gulfport, MS, USA

**Adeelia S. Goffe** German Primate Center, Göttingen, Germany

**Ilan Golani** School of Zoology, and Sagol School for Neuroscience, Tel Aviv University, Tel Aviv, Israel

**André Gonçalves** Language and Intelligence Section, Primate Research Institute, Kyoto University, Inuyama, Japan

**Clayton Gonçalves** Laboratório de Entomologia, Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**Fernando Gonçalves** Department of Ecology, São Paulo State University (UNESP), Rio Claro, São Paulo, Brazil

**Juan-Carlos Gómez** School of Psychology and Neuroscience, University of St. Andrews, St. Andrews, UK

**Miguel Angel Gómez-Serrano** Generalitat Valenciana-VAERSA, Valencia, Spain

**Tamara Gómez-Moracho** Research Center on Animal Cognition (CRCA), Center for Integrative Biology (CBI); CNRS, University Paul Sabatier, Toulouse, France

**Miranda Goodman-Wilson** Eckerd College, St. Petersburg, FL, USA

**Swanne P. Gordon** Department of Biological and Environmental Sciences, Center of Excellence in Biological Interactions, University of Jyväskylä, Jyväskylä, Finland

**Binita Goswami** Department of Biochemistry, Maulana Azad Medical College, New Delhi, India

**Shubham Goyal** Maulana Azad Medical College, New Delhi, India

**Gaute Grønstøl** Natural History Museum, University of Oslo, Oslo, Norway

**Paul Graham** School of Life Sciences, University of Sussex, Brighton, UK

**Michael C. Granatosky** Department of Organismal Biology and Anatomy, University of Chicago, Chicago, IL, USA

Department of Anatomy, College of Osteopathic Medicine, New York Institute of Technology, Old Westbury, NY, USA

**Gary Greenberg** Wichita State University, Wichita, KS, USA

**Brittany D. B. Greene** Independent Researcher, Suffolk, VA, USA

**Victor F. Gregori** Laboratório de Anatomia Comparativa de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, DF, Brazil

**Simon Grendeus** Cognitive Zoology Group, Cognitive Science, Department of Philosophy, Lund University, Lund, Sweden

**Andrea S. Griffin** School of Psychology, University of Newcastle, Callaghan, NSW, Australia

**Julie Gros-Louis** Department of Psychological and Brain Sciences, University of Iowa, Iowa City, IA, USA

**Laura Gruss** Department of Biology, Radford University, Radford, VA, USA

**David Guez** College of Healthcare Sciences, James Cook University, Smithfield, QLD, Australia

**Gabby Neves Guilhon** Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

**Nosheen Gul** Northern Illinois University, DeKalb, IL, USA

**Lindsey Gulick** Drexel University, Philadelphia, PA, USA

**Jamey Gulson** National Zoological Garden, South African National Biodiversity Institute, Pretoria, South Africa

**Tabitha Gunnars** Department of Integrative Biology, Oklahoma State University, Stillwater, OK, USA

**Aditi Gupta** New York Institute of Osteopathic Medicine, Old Westbury, NY, USA

**Anshul Gupta** Biochemistry, All India Institute of Medical Sciences, New Delhi, India

**Minoti Gupta** Panjab University, Chandigarh, India

**Richa Gupta** Department of Anatomy, PGIMER, Chandigarh, India

**Sonali N. Gupta** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Sumeet Gupta** Panjab University, Chandigarh, India

**Swati Gupta** Periodontist, Gainesville, IL, USA

**Satvinder K. Guru** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Germán Gutiérrez** Department of Psychology, National University of Colombia, Bogota, Colombia

**Valeria E. Gutiérrez-Ferre** Universidad Nacional de Educación a Distancia (UNED), Madrid, Spain

**Cristián Gutiérrez-Ibáñez** Neuroscience and Mental Health Institute, University of Alberta, Edmonton, AB, Canada

**Naiem Habib** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Krista Hagan** Department of Zoology and Physiology, University of Wyoming, Laramie, WY, USA

**Emily Hall** Department of Biological Sciences, Lehigh University, Bethlehem, PA, USA

**Robert Halpern** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Hira Hameed** Department of Biosciences, COMSATS Institute of Information Technology, Islamabad, Pakistan

**Robert R. Hampton** Yerkes National Primate Research Center and Department of Psychology, Emory University, Atlanta, GA, USA

**Pepper Hanna** Lynchburg College, Lynchburg, VA, USA

**Joerg Hardege** Department of Biology, School of Environmental Sciences, University of Hull, Hull, UK

**Heidi E. Harley** Psychology, New College of Florida, Sarasota, FL, USA

**David A. T. Harper** Palaeoecosystems Group, Department of Earth Sciences, Durham University, Durham, UK

**Lindsay N. Harris** Northern Illinois University, DeKalb, IL, USA

**Rachel A. Harrison** University of St Andrews, St Andrews, Scotland, UK  
University of Lausanne, Lausanne, Switzerland

**Steven J. Harrison** Center for the Ecological Study of Perception and Action, University of Connecticut, Storrs, CT, USA

**Genevra Hart** School of Psychology, University of New South Wales, Sydney, Australia

**Naomi D. Harvey** School of Veterinary Medicine and Science, The University of Nottingham, Sutton Bonington, UK

**Elizabeth Haseltine** Georgia State University, Atlanta, GA, USA

**Michael Haslam** University of Oxford, Oxford, UK

**Ahmad Hassan** Department of Neuroscience, Yale University School of Medicine, New Haven, CT, USA

**Jennifer Hegedus** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Monika Heikrujam** Department of Botany, Maitreyi College, University of Delhi, New Delhi, Delhi, India

**Rie Henriksen** AVIAN Behavioural Physiology and Genomics Group, IFM Biology, Linköping University, Linköping, Sweden

**Skyler Hensarling** Mississippi State University, Starkville, MS, USA

**Jonathan M. Henshaw** Department of Biological Sciences, University of Idaho, Moscow, ID, USA

Division of Ecology and Evolution, Research School of Biology, The Australian National University, Canberra, ACT, Australia

**Fábio Hepp** Laboratório de Anfíbios e Répteis, Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**Walter T. Herbranson** Whitman College, Walla Walla, WA, USA

**Suzana Herculano-Houzel** Vanderbilt University, Nashville, TN, USA

**Raúl Hernández-Pérez** Universidad Nacional Autónoma de México, Queretaro, Mexico

- Cecilia Heyes** University of Oxford, Oxford, UK
- James P Higham** New York University, New York, NY, USA
- J. Dee Higley** Brigham Young University, Provo, UT, USA
- Heather M. Hill** Psychology Department, St. Mary's University, San Antonio, TX, USA
- Heather M. Hill** St. Mary's University, San Antonio, TX, USA
- Robert L. Hill** Zoo Atlanta, Atlanta, GA, USA
- Jacqueline Hill Tudor** Ohio University, Lancaster, OH, USA
- Daniel Hipp** Eastern Colorado Health Center, Denver, CO, USA  
University of Colorado School of Medicine, Aurora, CO, USA
- André Hoffmann** Departamento de Biologia Geral, UFF, Niterói, RJ, Brazil
- Karen L. Hollis** Mount Holyoke College, South Hadley, MA, USA
- Jeannine Holmes** York University, Toronto, ON, Canada
- Per Holth** Oslo Metropolitan University, Oslo, Norway
- Andrew M. Holub** Department of Psychology, Oakland University, Rochester, MI, USA
- Lydia M. Hopper** Lester E. Fisher Center for the Study and Conservation of Apes, Lincoln Park Zoo, Chicago, IL, USA
- Scott Hooper** Zoo Atlanta, Atlanta, GA, USA
- William J. E. Hoppitt** School of Biology, University of Leeds, Leeds, UK
- Kristina Horback** University of California, Davis, CA, USA
- Emma L. Horton** Oxford Brookes University, Oxford, UK
- Katherine Albro Houghton** Cornell University, Ithaca, NY, USA
- Pengzhen Huang** School of Psychology, University of Lincoln, Lincoln, UK  
School of Life Sciences, East China Normal University, Shanghai, China

- Mercedes Hughes** Oakland University, Rochester, MI, USA
- Kevin D. Hunt** Anthropology Department, Indiana University, Bloomington, IN, USA

**Sarah M. Huskisson** Lester E. Fisher Center for the Study and Conservation of Apes, Lincoln Park Zoo, Chicago, IL, USA

**Rama Hussein** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Robert Hutton** Oakland University, Rochester Hills, MI, USA

**Sam Hyde Roberts** Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

**Esperanza Ibáñez-Jiménez** Department of Psychology, University of Chile, Santiago, Chile

**I. R. Inglis** Central Science Laboratory, York, UK

**Callen M. Inman** Department of Integrative Biology, University of Texas-Austin, Austin, TX, USA

**Donna Irvan** Oakland University, Rochester, MI, USA

**George Istafanos** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Soumya Iyengar** National Brain Research Centre, Manesar, Gurugram, Haryana, India

**Priya A. Iyer-Eimerbrink** University of North Texas at Dallas, Dallas, TX, USA

**Claire C. Jackman** Department of Psychological Sciences, Kent State University, Kent, OH, USA

**Brooke N. Jackson** Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

**Robert R. Jackson** School of Biological Sciences, University of Canterbury, Christchurch, New Zealand

International Centre of Insect Physiology and Ecology, Mbita Point, Kenya

**Seelia Jacob** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Gerald H. Jacobs** Department of Psychological and Brain Sciences, University of California, Santa Barbara, CA, USA

**Ivo Jacobs** Department of Cognitive Science, Lund University, Lund, Sweden

**Ayush Jain** Seth G S Medical College, Mumbai, India

**Buddhi Prakash Jain** Department of Zoology, Mahatma Gandhi Central University Bihar, Motihari, India

**Tripta Jain** Department of Botany, University College of Science, Mohanlal Sukhadia University, Udaipur, Rajasthan, India

**Damini Jaiswal** Department of Chemical Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, Maharashtra, India

**Brielle James** Georgia State University, Atlanta, GA, USA

**Rachel M. James** Department of Psychology, Oakland University, Rochester, MI, USA

**Cristina Jasso del Toro** Nocturnal Primate Research Group, Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

**Greg Jensen** Columbia University, New York, NY, USA

**Thomas Rejsenhus Jensen** Cognitive Zoology Group, Cognitive Science, Department of Philosophy, Lund University, Lund, Sweden

**Stephanie E. Jett** Georgia College and State University, Milledgeville, GA, USA

**Abhimanyu Kumar Jha** Department of Biotechnology, Faculty of Life Sciences, Institute of Applied Medicines and Research, Ghaziabad, UP, India  
Department of Biotechnology, IMS Engineering College, Ghaziabad, UP, India

Department of Biotechnology, School of Engineering and Technology, Sharda University, Greater Noida, India

**Meenakshi Jha** Department of Zoology, Delhi University, Delhi, India

**Zhou Jiang** School of Life Sciences, Guizhou Normal University, Guizhou, China

**Jing Jin** Key Laboratory of Advanced Control and Optimization for Chemical Processes, Ministry of Education, East China University of Science and Technology, Shanghai, China

**Jenson M. John** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Prescilla John** United States Army, New York, NY, USA

**Vimala K. John** Research and PG Department of Zoology, St. Thomas' College, Thrissur, India

**Jennifer M. Johnson** Georgia State University, Atlanta, GA, USA

**Kali Johnson** Department of Animal and Dairy Sciences, Mississippi State University, Mississippi State, MS, USA

**Melissa Johnston** Department of Psychology, University of Otago, Dunedin, New Zealand

**Adam G. Jones** Department of Biological Sciences, University of Idaho, Moscow, ID, USA

**Nick A. R. Jones** Centre for Social Learning and Cognitive Evolution, School of Biology, University of St. Andrews, St Andrews, UK

**Sarah N. Jones** Department of Counseling and Psychology, Tennessee Technological University, Cookeville, TN, USA

**Christelle Jozet-Alves** UMR 6552 EthoS Ethologie animale et humaine, Normandie Université, Unicaen, Caen, France  
Université de Rennes – CNRS, Rennes, France

**Bahareh Jozranjbar** Icelandic Vision Lab, Department of Psychology, University of Iceland, Reykjavik, Iceland

**JohnMichael Jurgensen** Department of Mathematics and Statistics, Boston University, Boston, MA, USA  
Department of Philosophy, Boston University, Boston, MA, USA

**Stefano S. K. Kaburu** Department of Population Health and Reproduction, School of Veterinary Medicine, University of California, Davis, CA, USA

**Farnaz Kaighobadi** Department of Social Sciences, Bronx Community College, City University New York, Bronx, NY, USA

**Stephen M. Kajiura** Department of Biological Sciences, Florida Atlantic University, Boca Raton, FL, USA

**Chinthaka D. Kaluthota** Behaviour and Evolution Research Group, Department of Psychology, University of Lethbridge, Lethbridge, AB, Canada

**Kapil Devidas Kamble** Sant Gadge Baba Amravati University, Amravati, India

**Yoshitaka Kamimura** Department of Biology, Keio University, Yokohama, Japan

**Lucas Augusto Kaminski** Departamento de Zoologia, Programa de Pós-Graduação em Biologia Animal, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil

**Gisela Kaplan** School of Science and Technology, University of New England, Armidale, NSW, Australia

**Subhradip Karmakar** Department of Biochemistry, All India Institute of Medical Sciences, New Delhi, India

**B. Katherine Smith** The University of Southern Mississippi, Hattiesburg, MS, USA

**Jeffrey S. Katz** Department of Psychology, Auburn University, Auburn, AL, USA

**Jaskirat Kaur** Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Manpreet Kaur** Hofstra University, Hewlett, NY, USA

**Stephanie A. Kazanas** Department of Counseling and Psychology, Tennessee Technological University, Cookeville, TN, USA

**Katherine Keck** University of St Andrews, St Andrews, UK

**Almut Kelber** Lund Vision Group, Department of Biology, Lund University, Lund, Sweden

**Andrew J. Kelly** Georgia Gwinnett College, Lawrenceville, GA, USA

**Debbie M. Kelly** Department of Psychology, University of Manitoba, Winnipeg, MB, Canada

**Laura A. Kelley** Centre for Ecology and Conservation, University of Exeter, Penryn, Cornwall, UK

**Abigail G. Kern** Covenant College, Lookout Mountain, GA, USA

**Sharon E. Kessler** Durham University, Durham, UK

**Jozef Keulartz** Philosophy Group, Wageningen University and Research, Wageningen, The Netherlands

**Ahmed A. Khalil** Charité – Universitätsmedizin Berlin, Berlin, Germany  
Berlin School of Mind and Brain, Humboldt-Universität zu Berlin, Berlin, Germany

Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany

**Kanza Khan** Department of Psychology, University of Southern Mississippi, Hattiesburg, MS, USA

**Madiha Khan** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Tarab Khan** Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Carolyn M. King** University of Waikato, Hamilton, New Zealand

**Glenn E. King** Department of History and Anthropology, Monmouth University, West Long Branch, NJ, USA

**Ildikó Király** Eötvös Loránd University, Budapest, Hungary

**Kimberly Kirkpatrick** Department of Psychological Sciences, Kansas State University, Manhattan, KS, USA

**Dmitry Kishkinev** Bangor University, Bangor, Gwynedd, UK

**Dawn M. Kitchen** The Ohio State University, Columbus, OH, USA  
The Ohio State University – Mansfield, Mansfield, OH, USA

**Dawn M. Kitchen** Department of Anthropology, The Ohio State University, Columbus, OH, USA

The Ohio State University-Mansfield, Mansfield, OH, USA

**Scott Kivitz** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Julia Klaczko** Laboratório de Anatomia Comparada de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, Brazil

**Stephen B. Klein** Mississippi State University, Starkville, MS, USA

**Sander Klerk** Utrecht University, Utrecht, The Netherlands

**Peter H. Klopfer** Department of Biology, Duke University, Durham, NS, USA

**Mirjam Knörnschild** Animal Behavior Lab, Free University of Berlin, Berlin, Germany

Smithsonian Tropical Research Institute, Ancón, Panamá

Museum für Naturkunde – Leibniz Institute for Evolution and Biodiversity Science, Berlin, Germany

**Anastasiya Kobrina** Department of Psychology, University at Buffalo, SUNY, Buffalo, NY, USA

Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ, USA

**Daiani Kochhann** Center of Agrarian and Biological Sciences, State University of the Acaraú Valley, Sobral, Ceará, Brazil

**Andreas Koenig** Department of Anthropology, Stony Brook University SUNY, Stony Brook, NY, USA

**Matthew Kostecky** St. Joseph's College, University of Alberta, Edmonton, AB, Canada

**Mounica Kota** Department of Ecology, Evolution and Behavior, University of Minnesota, Falcon Heights, MN, USA

**Kurt Kotrschal** Department of Behavioral Biology and Konrad Lorenz Forschungsstelle Grünau, University of Vienna, Vienna, Austria

Wolf Science Center, University of Veterinary Science, Vienna, Austria

**Carla Krachun** University of Saskatchewan, Saskatoon, Canada

**Fanny-Linn H. Kraft** Centre for Integrative Ecology, Deakin University, Geelong, VIC, Australia

**Anastasia Krasheninnikova** Department of Behavioural Neurobiology, Max-Planck-Institute for Ornithology, Seewiesen, Germany

Max-Planck Comparative Cognition Research Group, Tenerife, Spain

Department of Behavioural Ecology and Evolutionary Genetics, Max-Planck-Institute for Ornithology, Seewiesen, Germany

**Stéphane Kraus** Research Center on Animal Cognition (CRCA), Center for Integrative Biology (CBI); CNRS, University Paul Sabatier, Toulouse, France

**Jesse S. Krause** Department of Neurobiology, Physiology, and Behavior, University of California, Davis, CA, USA

**Mark A. Krause** Department of Psychology, Southern Oregon University, Ashland, OR, USA

**Buddhamas Pralle Kriengwatana** University of St Andrews, St Andrews, Scotland

**Hare Krishna** Department of Anatomy, All India Institute of Medical Sciences (AIIMS), Jodhpur, Rajasthan, India

**Kavita Krishnamoorti** Genetics Laboratory, Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, India

**Bal Krishnan** Indian Institute of Science Education and Research Berhampur, Berhampur, Odisha, India

**Rachel E. Kristiansen** Department of Psychology, Sheridan College, Sheridan, WY, USA

**Aaron R. Krochmal** Department of Biology, Washington College, Chestertown, MD, USA

**Miha Krofel** Wildlife Ecology Research Group, Department of Forestry, Biotechnical Faculty, University of Ljubljana, SI, Ljubljana, Slovenia

**Konstanze Krueger** Faculty Agriculture, Economics and Management, Department Equine Economics, Nuertingen-Geislingen University, Nürtingen, Germany

Department of Zoology/Evolutionary Biology, University of Regensburg, Regensburg, Germany

**Christopher Krupenye** Department of Developmental and Comparative Psychology, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

**Barbora Kuběnová** Faculty of Agrobiological Sciences, Food and Natural Resources, Czech University of Life Sciences, Prague, Czech Republic

**Enikő Kubinyi** Department of Ethology, Eötvös Loránd University, Budapest, Hungary

**A. M. Kuczynski** Kirtland Community College, Roscommon, MI, USA

**Valerie A. Kuhlmeier** Queen's University, Kingston, ON, Canada

**Maheswari Kulandhasamy** Jawaharlal Institute of Postgraduate Medical Education and Research (JIPMER), Karaikal, Puducherry, India

Department of Biochemistry, Maulana Azad Medical College, New Delhi, India

**Ankit Kumar** Centre for Neural and Cognitive Sciences, School of Medical Sciences, University of Hyderabad, Hyderabad, India

**Ashutosh Kumar** Jawaharlal Institute of Postgraduate Medical Education and Research (JIPMER), Karaikal, Puducherry, India

Department of Anatomy, All India Institute of Medical Sciences (AIIMS), New Delhi, India

**Cash Kumar** Department of Zoology, Banaras Hindu University, Varanasi, India

**Dinesh Kumar** JIPMER, Puducherry, India

**Gaurav Kumar** Department of Environment Science, PGDAV College, University of Delhi, New Delhi, Delhi, India

**Pavan Kumar** Department of Anatomy, All India Institute of Medical Sciences (AIIMS), New Delhi, India

**Rahul Kumar** International Centre for Genetic Engineering and Biotechnology, New Delhi, India

Neurobiology Division, Defence Institute of Physiology and Allied Science (DIPAS), Defence Research and Development Organisation, Delhi, India

Pharmacology and Toxicology Department, National Institute of Pharmaceutical Education and Research, Hyderabad, India

**Sandeep Kumar** National Brain Research Centre, Manesar, Gurugram, Haryana, India

Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

**Sanjay Kumar** Department of Zoology, Banaras Hindu University, Varanasi, India

**Vivek Kumar** Department of Biotechnology, IMS Engineering College, Ghaziabad, India

**Umesh Kumar** Centre for Cellular and Molecular Biology, Hyderabad, India

**Chiman Kumari** Department of Anatomy, Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh, India

**Richa Kumari** National Institute of Immunology, New Delhi, India

**L. Tamara Kumpan** Anthropology, University of Toronto Scarborough, Toronto, ON, Canada

**Shannon Kunder** Department of Psychology and Counseling, Hood College, Frederick, MD, USA

**Akanksha Kushwaha** Department of Zoology, Banaras Hindu University, Varanasi, India

**Matías López** Department of Psychology, University of Oviedo, Oviedo, Spain

**Andrés López-Sepulcre** Institute of Ecology and Environmental Sciences (CNRS UMR 7618), Université Pierre et Marie Curie, Paris, France

**Gabriela E. López-Tolsa** Universidad Nacional Autónoma de México (UNAM), Ciudad de México, Mexico

**Mario A. Laborda** Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

**Garet P. Lahvis** Oregon Health and Science University, Portland, OR, USA

**Kevin N. Laland** University of St Andrews, St Andrews, UK

**Christine Lalonde** Northern Ontario School of Medicine, Laurentian University, Sudbury, ON, Canada

**Joanna E. Lambert** Departments of Anthropology and Environmental Studies, University of Colorado Boulder, Boulder, CO, USA

**Rodrigo Landabur** Department of Psychology, Faculty of Social Sciences, University of Chile, Santiago, Chile

**Florence Landry** Department of Anthropology, University of Toronto, Toronto, ON, Canada

**Blaine Landsborough** Department of Biology, McMaster University Hamilton, Ontario, Canada

**Jan Langbein** Institute of Behavioural Physiology, Leibniz Institute for Farm Animal Biology (FBN), Dummerstorf, Germany

**Samantha Lantz** Department of Ecology and Evolutionary Biology, Tulane University, New Orleans, LA, USA

**Fernando Larriva-Sánchez** Facultad de Química, Universidad Autónoma de Querétaro, Querétaro, México

**Luke C. Larter** University of Texas, Austin, TX, USA

**Kennon A. Lattal** Department of Psychology, West Virginia University, Morgantown, WV, USA

**Lisa Lauderdale** Chicago Zoological Society – Brookfield Zoo, Brookfield, IL, USA

**Koedi S. Lawley** Neuroscience Program, Department of Zoology and Physiology, University of Wyoming, Laramie, WY, USA

**Olga Lazareva** Drake University, Des Moines, IA, USA

**William T. Leach** Truman State University, Kirksville, MO, USA

**Ellouise Leadbeater** School of Biological Sciences, Royal Holloway University of London, Egham, UK

**Andrew Lear** Independent scholar, Watertown, MA, USA

**David A. Leavens** School of Psychology, University of Sussex, East Sussex, UK

**Jean-Baptiste Leca** Department of Psychology, University of Lethbridge, Lethbridge, AB, Canada

**Amanda Lechnar** Oakland University, Rochester, MI, USA

**Jenny Lee** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Sang Ah Lee** Department of Bio and Brain Engineering, Korea Advanced Institute of Science and Technology, Daejeon, South Korea

**Eric Legge** Department of Psychology, MacEwan University, Edmonton, AB, Canada

**Pierre Lemelin** Division of Anatomy, Department of Surgery, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada

**Ádám Z. Lendvai** Department of Evolutionary Zoology and Human Biology, University of Debrecen, Debrecen, Hungary

**Leah F. Leonard** Department of Forestry, Mississippi State University, Mississippi State, MS, USA

**Eric J. Leonardis** Department of Cognitive Science, University of California, San Diego, La Jolla, CA, USA

**Caroline Leuchtenberger** Federal Institute Farroupilha, Panambi, RS, Brasil

**Cary H. Leung** Widener University, Chester, PA, USA

**Patrick K. Lewtas** Department of Philosophy, American University of Beirut, Beirut, Lebanon

**Ming Fei Li** Department of Anthropology, University of Toronto, Toronto, ON, Canada

**Robert Lickliter** Department of Psychology, Florida International University, Miami, FL, USA

**Katja Liebal** Department of Education and Psychology, Comparative Developmental Psychology, Freie Universität Berlin, Berlin, Germany

**Mathieu Lihoreau** Research Center on Animal Cognition (CRCA), Center for Integrative Biology (CBI); CNRS, University Paul Sabatier, Toulouse, France

Research Center on Animal Cognition (CRCA), Research Center of Integrative Biology (CBI); University of Toulouse III, Toulouse, France

**Malin K. Lilley** The University of Southern Mississippi, Hattiesburg, MS, USA

**Malin Lilley** The University of Southern Mississippi, Hattiesburg, MS, USA

**Harvey B. Lillywhite** Department of Biology, University of Florida, Gainesville, FL, USA

**Jennifer K. Link** SUNY New Paltz, New Paltz, NY, USA

**David M. Logue** Behaviour and Evolution Research Group, Department of Psychology, University of Lethbridge, Lethbridge, AB, Canada

**Aida Longán** Centro de Estudios e Investigaciones en Comportamiento, Universidad de Guadalajara, Guadalajara, México

**Elizabeth V. Lonsdorf** Franklin & Marshall College, Lancaster, PA, USA

**Matthew I. M. Louder** Department of Psychology, City University of New York, New York, NY, USA

**Nathália Siqueira Veríssimo Louzada** Programa de Pós-graduação em Biodiversidade e Biologia Evolutiva, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Sandro Lovari** Dipartimento di Scienze della Vita, Università di Siena, Siena, Italy

**Melany W. Love** Georgia State University, Atlanta, GA, USA

**Sherry E. Loveless** Psychology of Animal Behavior and Conservation, Hunter College, City University of New York, New York, NY, USA

**Anna Loy** Envix Lab – Department Biosciences and Territory, University of Molise, Pesche, Italy

**David Luque** UNSW Sydney, Sydney, NSW, Australia

**Robert Lurz** Brooklyn College, CUNY, New York City, NY, USA

**J. Luzete** Laboratório de Anatomia Comparada de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, DF, Brazil

**Stephen J. Lycett** Department of Anthropology, University at Buffalo, Amherst, NY, USA

**Heidi Lyn** The University of Southern Mississippi, Long Beach, MS, USA

**Pamela Lyon** Southgate Institute for Health, Society and Equity, Flinders University of South Australia, Adelaide, SA, Australia

**Suzanne MacDonald** Department of Psychology, York University, Toronto, ON, USA

**Riley Macgregor** University of Southern Mississippi, Hattiesburg, MS, USA

**Armando Machado** University of Aveiro, Aveiro, Portugal

**Angela Mackey** Kentucky Wesleyan College, Owensboro, KY, USA

**Alexander Mackiel** Department of Psychology, State University of New York, New Paltz, New Paltz, NY, USA

**Laura MacLatchy** University of Michigan, Ann Arbor, MI, USA

**Krista Macpherson** Department of Psychology, Western University, London, ON, Canada

**Alaina Macri** The Royal Zoological Society of Scotland, Edinburgh, UK

**Heather B. Madsen** Behavioural Neuroscience Division, The Florey Institute of Neuroscience and Mental Health, Parkville, VIC, Australia

Florey Department of Neuroscience and Mental Health, University of Melbourne, Parkville, VIC, Australia

**Ignacio Maeso** Department of Gene Regulation and Morphogenesis, Andalusian Centre for Developmental Biology (CABD), CSIC/University Pablo de Olavide, Seville, Spain

**Lorenzo Magnani** Department of Humanities, Philosophy Section and Computational Philosophy Laboratory, University of Pavia, Pavia, Italy

**William E. Magnusson** Instituto Nacional de Pesquisas da Amazônia (INPA), Manaus, Amazonas, Brazil

**Christine R. Maher** Department of Biological Sciences, University of Southern Maine, Portland, ME, USA

**Bonaventura Majolo** School of Psychology, University of Lincoln, Lincoln, UK

**Jorge Mallea** Department of Psychology, Columbia University, New York, NY, USA

**Akash Mallick** Centre for Chemical Biology, CSIR-Indian Institute of Chemical Technology, Hyderabad, Telangana, India

**Elizabeth K. Mallott** Department of Anthropology, Northwestern University, Evanston, IL, USA

**John C. Malone** University of Tennessee, Knoxville, TN, USA

**Martina Manns** Division of Experimental and Molecular Psychiatry, Department of Psychiatry, Psychotherapy and Preventive Medicine, LWL University Hospital, Ruhr-University Bochum, Bochum, Germany

Biopsychology, Institute of Cognitive Neuroscience, Ruhr-University of Bochum, Bochum, Germany

**Marta B. Manser** Department of Evolutionary Biology and Environmental Studies, University of Zurich, Zurich, Switzerland

**Mallahalli S. Manu** Department of Biochemistry, Davangere University, Davangere, Karnataka, India

**Giorgio Manzi** Department of Environmental Biology, Sapienza Università di Roma, Rome, Italy

**Terry L. Maple** Georgia Tech (retired), Fernandina Beach, FL, USA

**Fatima Maqsood** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Ali Marchant** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Cécile Marcoz-Fellay** Université de Montréal, Montréal, Canada

**Lori Marino** The Kimmela Center for Animal Advocacy, Kanab, UT, USA

**Nicola Marples** Trinity College Dublin, Dublin, Ireland

**Isabell Marr** Behavioural Physiology of Farm Animals, University of Hohenheim, Stuttgart, Germany

Faculty Agriculture, Economics and Management, Department Equine Economics, Nuertingen-Geislingen University, Nürtingen, Germany

**Consuelo San Martín** Universidad de Chile, Santiago, Chile

**Julien G. A. Martin** School of Biological Sciences, University of Aberdeen, Aberdeen, UK

**Graham R. Martin** School of Biosciences, University of Birmingham, Birmingham, UK

**Rowan O. Martin** Africa Conservation Programme, World Parrot Trust, Hayle, UK

FitzPatrick Institute of African Ornithology, University of Cape Town, Cape Town, South Africa

**Hausberger Martine** UMR 6552, Laboratoire d'éthologie animale et humaine, Campus de Beaulieu, CNRS, Université de Rennes 1, Université de Caen Normandie, Rennes, France

**Angele R. Martins** Laboratório de Anatomia Comparativa de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, DF, Brazil

Setor de Herpetologia, Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**Jorg J. M. Massen** Department of Cognitive Biology, University of Vienna, Vienna, Austria

Austrian Research Center for Primatology, Landskron, Austria

Animal Behaviour and Cognition, Utrecht University, Utrecht, The Netherlands

**Matthew S. Matell** Department of Psychological and Brain Sciences, Villanova University, Villanova, PA, USA

**Jill M. Mateo** Department of Comparative Human Development, The University of Chicago, Chicago, IL, USA

**Jennifer A. Mather** University of Lethbridge, Lethbridge, AB, Canada

**Natalie A. Matheson** Department of Anatomy and the Brain Health Research Centre, University of Otago, Dunedin, New Zealand

**Runjhun Mathur** Dr. A.P.J Abdul Kalam Technical University, Lucknow, India

Department of Biotechnology, IMS Engineering College, Ghaziabad, UP, India

**Tetsuro Matsuzawa** Kyoto University, Kyoto, Japan

**Leslie Matuszewich** Northern Illinois University, DeKalb, IL, USA

**Louis D. Matzel** Department of Psychology, Rutgers University, Piscataway, NJ, USA

**Ganesh Kumar Maurya** Molecular Biology Division, Bhabha Atomic Research Centre, HBNI, Mumbai, India

**Caio Maximino** Laboratório de Neurociências e Comportamento, Grupo de Pesquisas em Neurofarmacologia e Psicopatologia Experimental, Instituto de Estudos em Saúde e Biológicas, Universidade Federal do Sul e Sudeste do Pará, Marabá, Brazil

**Richard May** Biology Program, Southern Oregon University, Ashland, OR, USA

**Jonathan Mayer** Department of Biology, New York Institute of Technology, Old Westbury, NY, USA

**Stella R. Mayerhoff** Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

**Sarah E. Maylott** University of Miami, Coral Gables, FL, USA

**Keely Q. Maynard** Oxford Brookes University, Oxford, UK

**Allan Mazur** Syracuse University, Syracuse, NY, USA

**Giuseppe Mazza** Consiglio per la Ricerca in Agricoltura e l'Analisi dell'Economia Agraria (CREA), Research Centre for Plant Protection and Certification (CREA-DC), Cascine del Riccio, Florence, Italy

**Richard McFarland** Department of Anthropology, University of Wisconsin-Madison, Madison, WI, USA

**Dillon J. McGovern** Department of Psychological and Brain Sciences, Villanova University, Villanova, PA, USA

**Ragen T. S. McGowan** Behavior and Welfare Section, Nestlé Purina, St. Louis, MO, USA

**Lucas McGranahan** Chicago, IL, USA

**Margo McGrath** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Anthony McGregor** Department of Psychology, Durham University, Durham, UK

**Andrew W. McHill** Oregon Institute of Occupational Health Sciences, Oregon Health and Science University, Portland, OR, USA

**Emma McKeon** Georgia State University, Atlanta, GA, USA

**Neil McMillan** University of Alberta, Edmonton, Alberta, Canada

**Kaylin McNulty** Mississippi State University, Mississippi State, MS, USA

**Mercedes McWaters** Northern Illinois University, DeKalb, IL, USA

**Madeleine K. Meehan** Department of Psychology, Oakland University, Rochester, MI, USA

**Mukesh Meena** Department of Botany, University College of Science, Mohanlal Sukhadia University, Udaipur, Rajasthan, India

Department of Botany, Institute of Science, Banaras Hindu University, Varanasi, India

**Andrea Megela Simmons** Department of Cognitive, Linguistic, and Psychological Sciences, Brown University, Providence, RI, USA

**Christina Meier** University of Manitoba, Winnipeg, MB, Canada

**Amanda D. Melin** Department of Anthropology and Archaeology, University of Calgary, Calgary, AB, Canada

**Dawn Melzer** Sacred Heart University, Fairfield, CT, USA

**Joseph R. Mendelson III** School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA, USA

Department of Research, Zoo Atlanta, Atlanta, GA, USA

**Charles R. Menzel** Georgia State University, Atlanta, GA, USA

**Emily J. E. Messer** School of Psychology and Neuroscience, University of St Andrews, St Andrews, Scotland, UK

**Claudia Mettke-Hofmann** School of Natural Sciences and Psychology, Liverpool John Moores University, Liverpool, UK

**Marnie Metzler** Carolinas Healthcare, Charlotte, NC, USA

**Nadia Miecznikowski** Zoo Atlanta, Atlanta, GA, USA

**Alexander Mielke** Primate Models for Behavioural Evolution Lab, Institute for Cognitive and Evolutionary Anthropology, Oxford, UK

**Gonzalo Miguez** Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

**Ádám Miklósi** Eötvös Loránd University, Budapest, Hungary

**Kelly D. Miller** Department of Biological Sciences, Edward J. Meeman Biological Station, and Center for Biodiversity Research, University of Memphis, Memphis, TN, USA

**Noam Miller** Wilfrid Laurier University, Waterloo, ON, Canada

**Megan E. Miller-Cahill** Department of Psychological Sciences, Kent State University, Kent, OH, USA

**Garrett W. Milliken** College of Charleston, Charleston, SC, USA

**Fayaz Ahmad Mir** School of Life Sciences, Jawaharlal Nehru University, New Delhi, India

**Shannon K. Mischler** Department of Psychology, University of Alberta, Edmonton, AB, Canada

**Alaknanda Mishra** National Institute of Immunology, New Delhi, India

**Nitesh Kumar Mishra** Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Pradeep Kumar Mishra** Institute for Stem Cell Biology and Regenerative Medicine, TIFR, GKVK, Bengaluru, Karnataka, India

**Santosh Kumar Mishra** Biotechnology, IMS Engineering College, Ghaziabad, India

**Shruti Mishra** Molecular Biology Division, Bhabha Atomic Research Centre, Mumbai, India

**Swati Mishra** Banaras Hindu university, Varanasi, India

**Swati Mishra Shukla** Banaras Hindu University, Varanasi, India

**Ralph Mistlberger** Simon Fraser University, Burnaby, BC, Canada

**Robert W. Mitchell** Department of Psychology, Eastern Kentucky University, Richmond, KY, USA

**Joseph C. Mitchell** Florida Museum of Natural History, University of Florida, Gainesville, FL, USA

**Sankat Mochan** Department of Anatomy, All India Institute of Medical Sciences (AIIMS), New Delhi, India

**Klaudia Modlinska** Institute of Psychology, Polish Academy of Sciences, Warsaw, Poland

**Bhagyalaxmi Mohapatra** Cytogenetics Laboratory, Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Andrés Molero-Chamizo** Department of Psychology, University of Huelva, Huelva, Spain

**Mikael Molet** University of Lille, Villeneuve-d'Ascq, France

**Coline Monchanin** Research Center on Animal Cognition (CRCA), Center for Integrative Biology (CBI); CNRS, University Paul Sabatier, Toulouse, France

**Giovanni B. Moneta** School of Social Sciences – Psychology, London Metropolitan University, London, UK

**Debra P. Moore** The Institute for Marine Mammal Studies (IMMS), Gulfport, MS, USA

**Mary Kate Moore** Department of Psychology, Armstrong State University, Savannah, GA, USA

**Cristiano R. Moreira** Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**Kelsey Moreno** University of Southern Mississippi, Hattiesburg, MS, USA

**Kathleen N. Morgan** Wheaton College, Norton, MA, USA

**David Morgan** Lester E. Fisher Center for the Study and Conservation of Apes, Chicago, IL, USA

**Emiliano Mori** Dipartimento di Scienze della Vita, Università di Siena, Siena, Italy

**Rachel Morrison** Department of Psychology, University of North Carolina at Pembroke, Pembroke, NC, USA

**Rohini Motwani** Department of Anatomy, ESIC Medical College, Hyderabad, India

**S. Mucha** Department of Biology, Humboldt-Universität, Berlin, Germany

**Jen Muir** Department of Social Sciences, Oxford Brookes University, Oxford, UK

**Indrani Mukherjee** All India Institute of Medical Sciences, New Delhi, India

Amity Institute of Biotechnology, Amity University, Noida, Uttar Pradesh, India

**Vijaykumar Yogesh Muley** Centre for Computational Sciences, School of Basics and Applied Sciences, Central University of Punjab, Bathinda, Punjab, India

Instituto de Neurobiología, Universidad Nacional Autónoma de México, Querétaro, Mexico

**Hannah Mull** Kentucky Wesleyan College, Owensboro, KY, USA

**Christina A. S. Mumm** Animal Behavior Lab, Free University of Berlin, Berlin, Germany

**Gustavo Munro** Department of Psychology, University of Chile, Santiago, Chile

**Joseph Muraca** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Gwendolyn K. Murdock** Psychology and Counseling, Pittsburg State University, Pittsburg, KS, USA

**Matthew Murphy** Department of Psychology, Coastal Carolina University, Conway, SC, USA

**David J. Murray** Department of Psychology, Queen's University, Kingston, ON, Canada

**Roberta A. Murta-Fonseca** Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**Alyson Myers** Florida Atlantic University, Boca Raton, FL, USA

**Ali Nabavizadeh** Cooper Medical School of Rowan University, Camden, NJ, USA

**S. Nagaraj** Jipmer, Karaikal, India

**James S. Nairne** Department of Psychological Sciences, Purdue University, West Lafayette, USA

**Atindra Narayan** Medicine, ESI Model Hospital, Delhi, India

**Ravi Kant Narayan** Department of Anatomy, All India Institute of Medical Sciences (AIIMS), Patna, India

**Arshan Nasir** Department of Biosciences, COMSATS Institute of Information Technology, Islamabad, Pakistan

Evolutionary Bioinformatics Laboratory, Department of Crop Sciences, University of Illinois at Urbana-Champaign, Urbana, IL, USA

**Antón Navarro** Universidad de Oviedo, Oviedo, Spain

**Christian Nawroth** Institute of Behavioural Physiology, Leibniz Institute for Farm Animal Biology (FBN), Dummerstorf, Germany

**Heather W. Neave** Animal Welfare Program, Faculty of Land and Food Systems, University of British Columbia, Vancouver, BC, Canada

**Neelabh** Department of Biotechnology, SR Institute of Management and Technology, Lucknow, Uttar Pradesh, India

Department of Zoology (MMV), Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

**Neha** Laboratory of Molecular Ecology, Department of Botany, Banaras Hindu University, Varanasi, India

**Patrick Neilands** The University of Auckland, Auckland, New Zealand

**K. Anne-Isola Nekaris** Nocturnal Primate Research Group, Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

**Elaine M. Newbern** Eckerd College, St. Petersburg, FL, USA

**Chris Newman** Wildlife Conservation Research Unit, Department of Zoology, University of Oxford, The Recanati-Kaplan Centre, Oxford, UK

**F. Nghakliana** Department of Zoology, Mizoram University, Mizoram, India

**Nadia Nieves** The New School for Social Research, New York, NY, USA

**Ivan Norscia** Natural History Museum, University of Pisa, Pisa, Italy  
Department of Life Sciences and System Biology, University of Torino, Torino, Italy

**Rahel Noser** Cognitive Ethology Lab, German Primate Center, Göttingen, Germany

**Viviane C. S. Nunes** Programa de Pós-Graduação em Biologia Evolutiva e do Desenvolvimento (BED), Faculdade de Ciências, Universidade de Lisboa, Lisbon, Portugal

Computational Biology and Population Genomics Group (COBIG2), Centro de Biologia Ambiental, Departamento de Biologia Animal, Faculdade de Ciências, Universidade de Lisboa, Lisbon, Portugal

**Howard C. Nusbaum** Department of Psychology, The University of Chicago, Chicago, IL, USA

**Victoria L. O'Connor** Oakland University, Rochester, MI, USA

**Cathal O'Madagain** Department of Developmental and Comparative Psychology, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

**Eóin P. O'Sullivan** The University of Stirling, Stirling, UK

**Lenin D. Ochoa-de la Paz** Unidad de Investigación APEC-UNAM, Departamento de Bioquímica, Facultad de Medicina, Universidad Nacional Autónoma de México, México City, Mexico

**Satoshi Ogawa** Brain Research Institute Monash Sunway (BRIMS), Jeffrey Cheah School of Medicine and Health Sciences, Monash University Malaysia, Sunway, Selangor, Malaysia

**Sanae Okamoto-Barth** Faculty of Psychology and Neuroscience, Maastricht University, Maastricht, The Netherlands

**Katalin Oláh** Eötvös Loránd University, Budapest, Hungary

**I. F. Oliveira** Laboratório de Anatomia Comparada de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, DF, Brazil

**Rachel Olzer** Department of Ecology, Evolution and Behavior, University of Minnesota, Falcon Heights, MN, USA

**Naomi Ondrasek** UC Davis, Davis, CA, USA

**Pavlna Opatová** Institute of Vertebrate Biology, Czech Academy of Sciences, Brno, Czech Republic

**Wilson Aparecido Orcini** University Sagrado Coração (USC), Bauru, SP, Brazil

**Xavier G. Ordóñez** Complutense University of Madrid, Madrid, Spain

**Jason M. Organ** Indiana University School of Medicine, Indianapolis, IN, USA

Indiana University – Purdue University, Indianapolis, IN, USA

**Alex C. Orille** Oakland University, Rochester, MI, USA

**Emily Orlikoff** University of Michigan, Ann Arbor, MI, USA

**Britta Osthaus** School of Psychology, Politics and Sociology, Canterbury Christ Church University, Canterbury, UK

**Mathias Osvath** Cognitive Zoology Group, Cognitive Science, Department of Philosophy, Lund University, Lund, Sweden

**Eduardo B. Ottoni** Department of Experimental Psychology, University of São Paulo, São Paulo, SP, Brazil

**Anne Overduin-de Vries** Utrecht University, Utrecht, The Netherlands

**J. Bruce Overmier** University of Minnesota, Minneapolis, MN, USA

**James A. Oxley** Independent Researcher, Measham, Swadlincote, UK

**Shikha Pachauri** Nuclear Agriculture and Biotechnology Division, Bhabha Atomic Research Centre, Mumbai, India

**Lisa M. Paciulli** North Carolina State University, Raleigh, NC, USA

**Adam A. Pack** Departments of Psychology and Biology, University of Hawaii at Hilo, Hilo, HI, USA

The Dolphin Institute, Hilo, HI, USA

**F. Paglieri** Goal-Oriented Agents Lab, Istituto di Scienze e Tecnologie della Cognizione, CNR, Rome, Italy

**Debojyoti Pal** Radiation Biology and Health Sciences Division, Bio-Science Group, Bhabha Atomic Research Centre, Trombay, Mumbai, Maharashtra, India

**Elisabetta Palagi** Natural History Museum, University of Pisa, Pisa, Italy

**Brittney Palode** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Josefa N. S. Pandeirada** Department of Education and Psychology, University of Aveiro, Aveiro, Portugal

William James Center for Research, University of Aveiro, Aveiro, Portugal

Department of Psychological Sciences, Purdue University, West Lafayette, USA

CINTESIS.UA, University of Aveiro, Aveiro, Portugal

**Akanksha Pandey** Cytogenetics Lab, Department of Zoology, Banaras Hindu University, Varanasi, UP, India

**Sangeeta Panicker** American Psychological Association, Washington, DC, USA

**M. Paoletti** Dipartimento di Psicologia, Sapienza University, Rome, Italy

**Mauricio R. Papini** Department of Psychology, Texas Christian University, Fort Worth, TX, USA

**Jacob Pappas** Psychology, Oakland University, Rochester, MI, USA

**Matthieu Paquet** Department of Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden

**Hashim Paracha** Department of Biology, New York Institute of Technology, Old Westbury, NY, USA

**Luis Pardo** Department of Psychology, University of Chile, Santiago, Chile

**Vikas Pareek** Computational Neuroscience and Neuroimaging Division, National Brain Research Centre (NBRC), Manesar, Haryana, India

**Danielle Parente** Instituto de Física da, Universidade de Brasília, Brasília, DF, Brazil

**Ishwar Parhar** Brain Research Institute Monash Sunway (BRIMS), Jeffrey Cheah School of Medicine and Health Sciences, Monash University Malaysia, Sunway, Selangor, Malaysia

**Elizabeth Park** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Felipe Parrado** Facultad de Ciencias Sociales y Humanas, Universidad Surcolombiana, Neiva, Colombia

**Audrey E. Parrish** Department of Psychology, The Citadel, Charleston, SC, USA

**John J. Parrish** Department of Animal Sciences, University of Wisconsin-Madison, Madison, WI, USA

**Zachary T. Parsley** Department of Counseling and Psychology, Tennessee Technological University, Cookeville, TN, USA

**Thomas Parsons** University of Pennsylvania, Kennett Square, PA, USA

**Ágatha A. Paschoal** Laboratório de Anatomia Comparativa de Vertebrados, Departamento de Ciências Fisiológicas, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, DF, Brazil

**Cristian Pasquaretta** Research Center on Animal Cognition (CRCA), Research Center of Integrative Biology (CBI); University of Toulouse III, Toulouse, France

**Daniel C. Passos** Laboratório de Ecologia e Comportamento Animal, Departamento de Biociências, Centro de Ciências Biológicas e da Saúde, Universidade Federal Rural do Semi-Árido, Mossoró, RN, Brazil

**Murilo N. L. Pastana** Division of Fishes, Department of Vertebrate Zoology, National Museum of Natural History, Smithsonian Institution, Washington, DC, USA

**Shailaja Pathak** Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Amit Pathania** Micalis Institute, INRA, AgroParisTech, Université Paris-Saclay, Jouy-en-Josas, France

**Ashlesh Patil** Department of Physiology, All India Institute of Medical Sciences, Nagpur, MH, India

**Emily Patterson-Kane** Animal Welfare Division, American Veterinary Medical Association (AVMA), Schaumburg, IL, USA

**Billard Pauline** UMR 6552 EthoS Ethologie animale et humaine, Normandie Université, Unicaen, Caen, France  
Université de Rennes – CNRS, Rennes, France

**Mihaela Pavličev** Department of Pediatrics, Cincinnati Children's Hospital, Cincinnati, OH, USA

**Mateo Peñaherrera-Aguirre** Department of Psychology, University of Arizona, Tucson, AZ, USA

**Tina Peckmezian** Macquarie University, Sydney, NSW, Australia

**G. Pecora** Dipartimento di Psicologia Dinamica e Clinica, Sapienza University, Rome, Italy

**Ricardo Pellón** Universidad Nacional de Educación a Distancia (UNED), Madrid, Spain

**Sergio M. Pellis** Department of Neuroscience, University of Lethbridge, Lethbridge, AB, Canada

**Vivien C. Pellis** Department of Neuroscience, University of Lethbridge, Lethbridge, AB, Canada

**Chloe Peneaux** School of Psychology, University of Newcastle, Callaghan, NSW, Australia

**Irene M. Pepperberg** Department of Psychology, Harvard University, Cambridge, MA, USA

**Bonnie M. Perdue** Agnes Scott College, Atlanta, GA, USA

**Alfredo V. Peretti** Laboratorio de Biología Reproductiva y Evolución, F.C.E. F.N., Instituto de Diversidad y Ecología Animal, CONICET-UNC, Córdoba, Argentina

Universidad Nacional de Córdoba, Córdoba, Argentina

**Jonathan H. Pérez** Department of Neurobiology, Physiology, and Behavior, University of California, Davis, CA, USA

**Rita Luiza Peruquetti** University Sagrado Coração (USC), Bauru, SP, Brazil

**Daniel Marques Almeida Pessoa** Department of Physiology and Behavior, Universidade Federal do Rio Grande do Norte, Natal, Rio Grande do Norte, Brazil

**Irena Petak** Zagreb, Croatia

**Flávia F. Peteán** Instituto Tecnológico de Chascomús, Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) – Universidad Nacional General San Martín (UNSAM), Chascomús, Argentina

**Shane Peters** Hofstra University, Hicksville, NY, USA

**Shivani Peters** Hicksville, NY, USA

**Christian Petersen** Simon Fraser University, Burnaby, BC, Canada

**Rachel M. Petersen** New York University, New York, NY, USA

**Karthikeyan Pethusamy** Department of Biochemistry, All India Institute of Medical Sciences (AIIMS), New Delhi, India

**Zachary Piazza** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Anthony Piché** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Lorien Pichegru** Institute for Coastal and Marine Research, Nelson Mandela University, Port Elizabeth, South Africa

**David J. Piekarski** Psychology, University of California, Berkeley, Berkeley, CA, USA

**Graham J. Pierce** Instituto de Investigaciones Mariñas, CSIC, Vigo, Spain  
CESAM & Departamento de Biología, Universidade de Aveiro, Aveiro, Portugal

**Wojciech Pisula** Institute of Psychology, Polish Academy of Sciences, Warsaw, Poland

**Marichelle Renee T. Pita** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Sarah Piwetz** Dolphin Biology and Conservation, Cordenons, PN, Italy  
Texas A&M University at Galveston, Galveston, TX, USA

**David Pleurdeau** Département Homme and Environnement, UMR7194, Muséum national d'Histoire naturelle, CNRS, Paris, France

**Devon L. Poeta** Department of Cognitive, Linguistics and Psychological Sciences, Brown University, Providence, RI, USA

**Stephanie A. Poindexter** Department of Anthropology, SUNY Buffalo, Buffalo, NY, UK

**Eugenia Polizzi di Sorrentino** Institute of Cognitive Sciences and Technologies, National Research Council, Rome, Italy

**Elona Poltiylova** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Ori Pomerantz** California National Primate Research Center, Davis, CA, USA

**Blake Porter** Department of Psychology, University of Otago, Dunedin, New Zealand

**Cecily Portillo** Hofstra University, Hempstead, NY, USA

**Jessica Post** Institute for Marine Mammal Studies, Gulfport, MS, USA

**Melissa Postal** Instituto Federal de Educação, Ciência e Tecnologia Farroupilha, Panambi, Brazil

**Bonner Powell** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Kela Powell** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Alicia Pownall** Mississippi State University, Mississippi State, MS, USA

**Anubhav Pradeep** University of Illinois at Chicago, Chicago, IL, USA

**Sasha Prasad-Shreckengast** Department of Psychology, Hunter College, Thinking Dog Center, City University of New York, New York, NY, USA

**Jonathan F. Prather** Neuroscience Program, Department of Zoology and Physiology, University of Wyoming, Laramie, WY, USA

**Natalia Prieto** Hofstra University, Hempstead, NY, USA

**Nora H. Prior** Psychology/Biology, University of Maryland, College Park, College Park, MD, USA

**Anupam Priyadarshi** Department of Mathematics, Banaras Hindu University, Varanasi, India

**René T. Proyer** Department of Psychology, Martin Luther University Halle-Wittenberg, Halle, Germany

**Esther F. Pruitt** Covenant College, Lookout Mountain, GA, USA

**Ivan Puga-Gonzalez** Department of Ecology, Physiology and Ethology, Université de Strasbourg, CNRS, IPHC UMR 7178, Strasbourg, France

**Birger Puppe** Institute of Behavioural Physiology, Leibniz Institute for Farm Animal Biology (FBN), Dummerstorf, Germany  
Behavioural Sciences, Faculty of Agricultural and Environmental Sciences, University of Rostock, Rostock, Germany

**Lorenzo Quaglietta** CIBIO/InBio, Centro de Investigação em Biodiversidade e Recursos Genéticos, Universidade do Porto, Vairão, Portugal  
CEABN/InBio, Centro de Ecologia Aplicada “Professor Baeta Neves”, Instituto Superior de Agronomia, Universidade de Lisboa, Tapada da Ajuda, Lisboa, Portugal

**Vanetza E. Quezada-Scholz** Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

**Jorge A. Quillfeldt** Psychobiology and Neurocomputing Lab (LPBNC), Department of Biophysics, I.B., Neurosciences Graduate Program, ICBS, Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, RS, Brazil

**Mason L. Quinn** Tennessee Technological University, Cookeville, TN, USA

**Elena Racevska** Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

**Mary K. Radeke** Central Washington University, Ellensburg, WA, USA

**Manchala Raghunath** Endocrinology and Metabolism Division, National Institute of Nutrition (NIN), ICMR, Tarnaka, Hyderabad, India

**Pooja Rai** Department of Biotechnology, Faculty of Life Sciences, Institute of Applied Medicines and Research, Ghaziabad, UP, India

**Ankita Raj** Vardhman Mahavir Medical College, New Delhi, India

**Kundan Kishor Rajak** Department of Zoology, School of Life Sciences, Mahatma Gandhi Central University, Motihar, Bihar, India

**Singh Rajender** CSIR-Central Drug Research Institute, Lucknow, India

**Hannes Rakoczy** University of Göttingen, Göttingen, Germany

**Heather Rally** Captive Animal Law Enforcement, PETA Foundation, Norfolk, VA, USA

**Simón Ramírez** Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

**Gabriel Ramos-Fernandez** CIIDIR Unidad Oaxaca, Instituto Politecnico Nacional, Oaxaca, Mexico

Centro de Ciencias de la Complejidad, Universidad Nacional Autonoma de Mexico, Mexico, Mexico

**Bhisham Singh Rana** Department of Biotechnology, IMS Engineering College, Ghaziabad, UP, India

**Neha Rana** Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Madhavi Ranjan** Department of Life Sciences, Central University of Jharkhand, Brambe, Ranchi, India

**Shovit Ranjan** Department of Zoology, Miranda House, University of Delhi, Delhi, India

Centre for Life Sciences, School of Natural Science, Central University of Jharkhand, Brambe, Ranchi, Jharkhand, India

**Laurene M. Ratcliffe** Department of Biology, Queen's University, Kingston, ON, Canada

**Rebecca Rayburn-Reeves** Georgia Southern University – Armstrong Campus, Savannah, GA, USA

**Stephan A. Reber** Cognitive Zoology Group, Cognitive Science, Department of Philosophy, Lund University, Lund, Sweden

**Laura Alonso Recio** Universidad a Distancia de Madrid (UDIMA), Madrid, Spain

**Madeline Redd** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Jonathan Redshaw** Centre for Psychology and Evolution, School of Psychology, University of Queensland, St. Lucia, QLD, Australia

**Roger Reep** University of Florida, Gainesville, FL, USA

**Melissa A. L. Reggente** Dolphin Biology and Conservation, Cordenons, PN, Italy

**Cristiane B. Régis** Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Michael S. Reichert** School of Biological, Earth and Environmental Sciences, University College Cork, Cork, Ireland

**Colleen Reichmuth** Long Marine Laboratory, University of California Santa Cruz, Santa Cruz, CA, USA

**Lori Reider** Hofstra University, Long Island, USA

**Kathleen D. Reinhardt** Nocturnal Primate Research Group, Oxford Brookes University, Oxford, Headington, UK

**Diana Reiss** Department of Psychology, Hunter College of The City University of New York, New York, NY, USA

**Richard Remedios** Northcentral University, San Diego, CA, USA

**Luke Rendell** Centre for Social Learning and Cognitive Evolution, School of Biology, University of St. Andrews, St Andrews, UK

**Michael J. Renner** Drake University, Des Moines, IA, USA

**Qurat Ul Ain Reshi** Department of Pathophysiology, University of Tartu, Tartu, Estonia

**Jorge Retamal** Department of Psychology, University of Chile, Santiago, Chile

**John N. J. Reynolds** Department of Anatomy and the Brain Health Research Centre, University of Otago, Dunedin, New Zealand

**Marcelo Lopes Rheingantz** Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Beth Ann Rice** University of Kentucky, Lexington, KY, USA  
Department of Psychology, Slippery Rock University, Slippery Rock, PA, USA

**Robert J. Richards** Departments of History, Philosophy, and Psychology, The University of Chicago, Chicago, IL, USA

**Christina Riehl** Department of Ecology and Evolutionary Biology, Princeton University, Princeton, NJ, USA

**Nicoletta Righini** Laboratorio de Ecología Funcional, Instituto de Investigaciones en Ecosistemas y Sustentabilidad (IIES-UNAM), Morelia, Michoacán, Mexico

**Mallory Risinger** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Jorgo Ristevski** School of Biological Sciences, University of Queensland, Brisbane, QLD, Australia

**Ritu** Cytogenetics Laboratory, Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Sarah Ritvo** York University, Toronto, ON, Canada

**Danielle Rivet** Department of Biology, University of Saskatchewan, Saskatoon, SK, Canada

**Pamela D. Rivière** University of California, San Diego, CA, USA

**Pedro P. Rizzato** Laboratório de Ictiologia de Ribeirão Preto, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, Brazil

**Theresa Rößler** Comparative Cognition, Messerli Research Institute, University of Veterinary Medicine Vienna, Medical University of Vienna, University of Vienna, Vienna, Austria

Department of Cognitive Biology, University of Vienna, Vienna, Austria

**Haden Roberson** Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

**Bill Roberts** Western University, London, Ontario, Canada

**Richard G. Roberts** Centre for Archaeological Science, School of Earth, Atmospheric and Life Sciences, University of Wollongong, Wollongong, NSW, Australia  
Australian Research Council Centre of Excellence for Australian Biodiversity and Heritage, University of Wollongong, Wollongong, NSW, Australia

**William A. Roberts** Western University, London, ON, Canada

**Scott J. Robson** Queen's University, Kingston, ON, Canada

**Isabela Rocha** Museu Nacional UFRJ, Rio de Janeiro, RJ, Brazil

Laboratório de Entomologia, Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

**C. Rochais** Laboratoire Ethologie Animale et Humaine-EthoS- Université de Caen, Université de Rennes 1, UMR CNRS 6552, Paimpont, France

**Teresa Rodrigo** CCiTUB, Animal Research Unit of Psychology, Universitat de Barcelona, Barcelona, Spain

**Sanne Roelofs** Behaviour and Welfare Group (formerly Emotion and Cognition Group), Department of Farm Animal Health, Faculty of Veterinary Medicine, Utrecht University, Utrecht, The Netherlands

Brain Center Rudolf Magnus, Utrecht, The Netherlands

**Brett Roelofs** Molecular and Life Sciences, Curtin University, Perth, WA, Australia

**Kate Roelofs** Molecular and Life Sciences, Curtin University, Perth, WA, Australia

**Lesley J. Rogers** School of Science and Technology, University of New England, Armidale, NSW 2351, Australia

**Bibiana Rojas** Centre of Excellence in Biological Interactions, Department of Biological and Environmental Science, University of Jyväskylä, Jyväskylä, Finland

**Edmund T. Rolls** Oxford Centre for Computational Neuroscience, Oxford, UK

Department of Computer Science, University of Warwick, Coventry, UK

- Amelie Romain** University of Strasbourg, Strasbourg, France  
Bureau d'étude AKONGO, Toulon, France
- Sonia J. Romero** Madrid Open University, Madrid, Spain
- Teresa Romero** School of Live Sciences, University of Lincoln, Lincoln, UK
- Simon M. Rook** University of North Texas at Dallas, Dallas, TX, USA
- Marcello Rosa** Monash University, Clayton, VIC, Australia
- Juan M. Rosas** Universidad de Jaén, Jaén, Spain
- Kevin A. Rosenfield** Pennsylvania State University, University Park, PA, USA
- Dirleane O. Rossato** Department of Ecology, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil
- Timothy C. Roth II** Franklin and Marshall College, Lancaster, PA, USA
- Jessica M. Rothman** Department of Anthropology, Hunter College of the City University of New York, New York, NY, USA  
New York Consortium in Evolutionary Primatology, New York, NY, USA
- Misha Kyla Rowell** College of Science and Engineering, James Cook University, Cairns, QLD, Australia  
Centre for Tropical Environmental and Sustainability Sciences, James Cook University, Cairns, QLD, Australia
- Hannah M. Rowland** Max Planck Institute for Chemical Ecology, Jena, Germany
- Pratiti Roy** Department of Genetics and Plant Breeding (Plant Biotechnology), Banaras Hindu University, Varanasi, Uttar Pradesh, India
- R. Cyril Roy** Prairie Swine Centre, University of Saskatchewan, Saskatoon, Canada
- Selvi Roy** University of Prince Edward Island; Atlantic Council for International Cooperation, Charlottetown, PEI, Canada
- André Roza** Museu Nacional UFRJ, Rio de Janeiro, RJ, Brazil  
Laboratório de Entomologia, Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil
- Dustin R. Rubenstein** Department of Ecology, Evolution and Environmental Biology, Columbia University, New York, NY, USA
- Taylor L. Rubin** Zoo Atlanta, Atlanta, GA, USA
- Summer Rudish** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA
- Rosa Rugani** University of Padua, Padua, Italy

**Jordi Ruiz-Olmo** Generaliat de Catalunya, Barcelona, Spain

**Duane M. Rumbaugh** Georgia State University, Atlanta, GA, USA

**Chad Ruprecht** Microsoft Corporation, Redmond, WA, USA

**Mohd Uzair Rusli** School of Marine and Environmental Sciences, Universiti Malaysia Terengganu, Kuala Terengganu, Terengganu, Malaysia

**Yvan I. Russell** Middlesex University, London, UK

**Calen P. Ryan** Northwestern University, Evanston, IL, USA

**Tasmin Lee Rymer** College of Science and Engineering, James Cook University, Cairns, QLD, Australia

Centre for Tropical Environmental and Sustainability Sciences, James Cook University, Cairns, QLD, Australia

School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, Johannesburg, South Africa

**Gloria Sabbatini** Institute of Cognitive Sciences and Technologies, National Research Council, Rome, Italy

**Alexander Sacher** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Debasray Saha** Department of Biotechnology, Faculty of Life Sciences, Institute of Applied Medicines and Research, Ghaziabad, UP, India

**Eric Sidel** Philosophy Department, The George Washington University, Washington, DC, USA

**Angeles Salles** Johns Hopkins University, Baltimore, MD, USA

**Swarnmala Samal** Centre of Advanced Study in Botany, Institute of Science, Banaras Hindu University, Varanasi, India

**Ash Samuelson** School of Biological Sciences, Royal Holloway University of London, Egham, UK

**Derrick R. Samuelson** Department of Medicine, Section of Pulmonary/Critical Care and Allergy/Immunology, Louisiana State University Health Sciences Center, New Orleans, LA, USA

**Myстера M. Samuelson** Animal Behavior Core, Department of Comparative Medicine, The University of Nebraska Medical Center, Omaha, NE, USA

**Federico Sanabria** Arizona State University, Tempe, AZ, USA

**Andres F. Sanchez** Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

**Yongming Sang** Tennessee State University, Nashville, TN, USA

**Jarrett A. Sannerud** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**M. Begoña Santos** Centro Oceanográfico de Vigo, Instituto Español de Oceanografía, Vigo, Spain

**Laurie R. Santos** Department of Psychology, Yale University, New Haven, CT, USA

**Sangita Santra** The University of Burdwan, Burdwan, West Bengal, India

**Crickette Sanz** Washington University in St. Louis, Saint Louis, MO, USA

**Avik Sarkar** Department of Molecular Biology and Bioinformatics, Tripura University, Suryamaninagar, Tripura, India

**Sajib Kumar Sarkar** All India Institute of Medical Sciences (AIIMS), New Delhi, India

**Bruno Sauce** Department of Psychology, Rutgers University, Piscataway, NJ, USA

**Michael A. Savallo** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Aleksander B. Sawiec** Department of Mechanical Engineering, New York Institute of Technology, Old Westbury, NY, USA

**Jeremy Sawyer** Department of Psychology, The Graduate Center, CUNY, New York, NY, USA

**Katherine Saxton** Department of Biology, Santa Clara University, Santa Clara, CA, USA

**Damian Scarf** Department of Psychology, University of Otago, Dunedin, New Zealand

**Martin Schönfeld** University of South Florida, Tampa, FL, USA

**Wolfgang Schönpflug** Freie Universität Berlin, Berlin-Dahlem, Germany

**Wouter Schaake** University of Utrecht (Alumnus), Utrecht, The Netherlands

**Todd Schachtman** Psychological Sciences, University of Missouri, Columbia, MO, USA

**Rachel Schepke** Department of Psychology, Oakland University, Rochester, MI, USA

**Tiziana Scherrer** Department of Psychology, Martin Luther University Halle-Wittenberg, Halle, Germany

**Juan Scheun** National Zoological Garden, South African National Biodiversity Institute, Pretoria, South Africa

Mammal Research Institute, Department of Zoology and Entomology, University of Pretoria, Pretoria, South Africa

**Martin Schmelz** Department of Cognitive Biology, University of Vienna, Vienna, Austria

**Mark S. Schmidt** Department of Psychology, Columbus State University, Columbus, GA, USA

**Daniel Schmitt** Department of Evolutionary Anthropology, Duke University, Durham, NC, USA

**Nanette Y. Schneider** Centre de Recherche en Neurosciences de Lyon (Lyon Neuroscience Research Center) INSERM U1028, CNRS UMR 5292, Université Claude Bernard Lyon, Lyon, France

**Kathryn A. Schoenecker** U.S. Geological Survey, Fort Collins Science Center, Fort Collins, CO, USA

Department of Ecosystem Science and Sustainability, Colorado State University, Fort Collins, CO, USA

**Ryan K. Schott** Department of Ecology and Evolutionary Biology, University of Toronto, Toronto, ON, Canada

**Carsten Schradin** Université de Strasbourg, CNRS, IPHC UMR 7178, Strasbourg, France

School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, Johannesburg, South Africa

**Taylor Schudel** Department of Wildlife, Fisheries and Aquaculture, Mississippi State, MS, USA

**Patrick Schultheiss** Behavioural Physiology and Sociobiology (Zoology II), Biozentrum, University of Würzburg, Würzburg, Germany

**Andrew Schulz** Georgia Institute of Technology, Public university in Atlanta, Atlanta, GA, USA

**Sebastian Schwarz** Research Center on Animal Cognition (CRCA), Center for Integrative Biology (CBI); CNRS, University Paul Sabatier, Toulouse, France

**Erin N. Scully** Department of Psychology, University of Alberta, Edmonton, AB, Canada

**Jason Sears** Eckerd College, St. Petersburg, FL, USA

**Simimol Sebastian** Department of Zoology, Alphonsa College Pala, Kottayam District, Kerala, India

**Yolande M. Seddon** Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Canada

**Ashikh Seethy** Department of Biochemistry, All India Institute of Medical Sciences, New Delhi, India

**Ronen Segev** Zlotowski Center for Neuroscience, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Department of Life Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Department of Biomedical Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel

**Andrea R. Seitz** Mississippi State University, Mississippi State, MS, USA

**Michael S. Selby** Department of Biomedical Sciences, Georgia Campus-Philadelphia College of Osteopathic Medicine, Suwanee, GA, USA

**Scott W. Semenyina** University of Lethbridge, Lethbridge, AB, Canada

**Shaber A. Seraj** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Agnieszka Sergiel** Institute of Nature Conservation of Polish Academy of Sciences, Krakow, Poland

**Kishore Sesham** Department of Anatomy, All India Institute of Medical Sciences (AIIMS), Jodhpur, Rajasthan, India

**Henry Séverine** UMR 6552, Laboratoire d'éthologie animale et humaine, Station Biologique de Paimpont, Université de Rennes 1, Université de Caen Normandie, CNRS, Paimpont, France

**Todd K. Shackelford** Department of Psychology, Oakland University, Rochester, MI, USA

**Anu Sharma** Department of Biological Sciences, School of Basic and Applied Sciences, Dayananda Sagar University, Bangalore, Karnataka, India

**Dhirendra Kumar Sharma** Molecular Biology Division, Bhabha Atomic Research Centre, Mumbai, India

**Hitaishi Sharma** Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Kanika Sharma** Department of Botany, University College of Science, Mohanlal Sukhadia University, Udaipur, Rajasthan, India

**Kuldeep Sharma** Department of Botany, University College of Science, Mohanlal Sukhadia University, Udaipur, Rajasthan, India

**Vivek K. Sharma** Department of Physiology, Government Institute of Medical Sciences (GIMS), Greater Noida, Uttar Pradesh, India

Department of Physiology, Jawaharlal Institute of Postgraduate Medical Education and Research (JIPMER), Pondicherry, India

**Jessica L. Sharp** Department of Psychology, Davidson College, Davidson, NC, USA

**Heidi L. Shaw** Yakima Valley College, Yakima, WA, USA

**Steven A. Shea** Oregon Institute of Occupational Health Sciences, Oregon Health and Science University, Portland, OR, USA

OHSU-PSU School of Public Health, Oregon Health and Science University, Portland, OR, USA

**Alexander Paxton Thorn Shealy** Mississippi State University, College of Veterinary Medicine, Starkville, MS, USA

**Emily N. Shelton** Averett University, Danville, VA, USA

**Lauren E. Shields** Tennessee State University, Nashville, TN, USA

**Kazutaka Shinozuka** RIKEN Center for Brain Science, Wako, Saitama, Japan

**Devaraju Kuramkote Shivanna** Department of Biochemistry, Pavate Nagar, Karnatak University, Dharwad, India

**Vidya Shukla** Brain Research Laboratory, Biotechnology Unit, Department of Biosciences, Mangalore University, Mangalore, Karnataka, India

**Melissa Shyan-Norwalt** Department of Psychology, University of Cincinnati, Cincinnati, OH, USA

**Md. Abu Bokor Siddik** Department of Psychology, Rajshahi College, National University, Rajshahi, Bangladesh

**Monika Siekelova** University of Cambridge, Cambridge, UK

**Heida Maria Sigurdardottir** Icelandic Vision Lab, Department of Psychology, University of Iceland, Reykjavik, Iceland

**Francisco J. Silva** University of Redlands, Redlands, CA, USA

**Kathleen M. Silva** University of Redlands, Redlands, CA, USA

**Peter Simard** Environmental Studies Department, Eckerd College, St. Petersburg, FL, USA

**Rebecca Singer** Georgetown College, Georgetown, KY, USA

**A. K. Singh** Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

**Abhideep Singh** New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, USA

**Abhishek Kumar Singh** Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Abhishek Singh** Department of Botany, Banaras Hindu University, Varanasi, India

**Anuj Kumar Singh** Department of Skin and Venereal disease, LLRM Medical College, Meerut, India

**Archana Singh** Department of Biochemistry, All India Institute of Medical Sciences, New Delhi, India

**Divya Singh** School of Biotechnology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Gurvachan Singh** Genetics Laboratory, Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, India

**Karuna Singh** Department of Zoology (MMV), Banaras Hindu University, Varanasi, UP, India

**Kiran Singh** Department of Molecular and Human Genetics, Banaras Hindu University, Varanasi, India

**Poonam Singh** Zoology Section, Mahila Mahavidyalaya, Institute of Science, Banaras Hindu University, Varanasi, UP, India

**Roshni Singh** Genetics Laboratory, Department of Zoology, Institute of Sciences, Banaras Hindu University, Varanasi, India

**Shailesh Singh** Genetics Laboratory, Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

**Shashi Bala Singh** Pharmacology and Toxicology Department, National Institute of Pharmaceutical Education and Research, Hyderabad, India

**Sunil Singh** All India Institute of Medical Sciences, New Delhi, India

**Vertika Singh** Department of Molecular and Human Genetics, Banaras Hindu University, Varanasi, India

CSIR-Central Drug Research Institute, Lucknow, India

**Jitendra Kumar Sinha** CSIR – Centre for Cellular and Molecular Biology (CCMB), Hyderabad, Telangana, India

Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

**Marcello Siniscalchi** Department of Veterinary Medicine, University of Bari, Bari, Italy

**Penthai Siriwat** Oxford Brookes University, Oxford, UK

**Veronica Slobodian** Laboratório de Ictiologia Sistemática, Departamento de Zoologia, Instituto de Ciências Biológicas, Campus Universitário Darcy Ribeiro, Universidade de Brasília, Brasília, Brazil

**Emily M. Slonecker** Department of Psychology and Social Behavior, University of California, Irvine, Irvine, CA, USA

**Catherine E. Smith** Covenant College, Lookout Mountain, GA, USA

**Heather F. Smith** Department of Anatomy, Midwestern University, Glendale, AZ, USA

**J. David Smith** Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

**Kendal A. Smith** The University of Southern Mississippi, Hattiesburg, MS, USA

**Mackenzie F. Smith** Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

**Travis R. Smith** Georgia State University, Atlanta, GA, USA

**Sarah Snider** Zoo Atlanta, Atlanta, GA, USA

**Karla D. A. Soares** Laboratory of Ichthyology, Department of Zoology, University of São Paulo, São Paulo, Brazil

**Daphne Soares** Biological Sciences, New Jersey Institute of Technology, Newark, NJ, USA

**Gisela Sobral** Departamento de Reprodução Animal, Faculdade de Medicina Veterinária e Zootecnia, Universidade de São Paulo, São Paulo, Brazil

**João Augusto S. Sobral** Instituto de Física de São Carlos, Universidade de São Paulo, São Carlos, SP, Brazil

**Gabriela Sobral** Abteilung Paläontologie, Staatliches Museum für Naturkunde Stuttgart, Stuttgart, Germany

**Manuel Soler** Departamento de Zoología, Facultad de Ciencias, Unidad Asociada Coevolución: Cucos, Hospedadores y Bacterias Simbiontes, Universidad de Granada, Granada, Spain

**Sebastian Sosa** Anthropology Department, School of Sociology and Anthropology, Sun Yat-sen University, Guangzhou, China

**Meghan J. Sosnowski** Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

**Paula M. Souto** Departamento de Ciências e Engenharia de Biosistemas (DCEB), Instituto Superior de Agronomia, Universidade de Lisboa, Lisbon, Portugal

Museu Nacional, UFRJ, Rio de Janeiro, RJ, Brazil

Linking Landscape, Environment, Agriculture and Food (LEAF), Instituto Superior de Agronomia, Universidade de Lisboa, Lisbon, Portugal

[Ant bear](#); [Anteater](#); [Earth pig](#)

## Introduction

The aardvark (*Orycteropus afer*) is a burrowing quadruped nocturnal mammal that can be found across sub-Saharan Africa. People often mistakenly identify aardvarks as anteaters, and while ants are a primary part of their diet, aardvarks are a different taxonomic grouping and the only extant species in the order Tubulidentata. Aardvarks are an extremely reclusive species and are rarely observed in the wild. African folklore states that sighting an aardvark twice in your lifetime will lead to a long and happy existence (Knothig 2005).

The name aardvark originates from “aarde” meaning earth and “vark” meaning pig. The name is derived from the Afrikaans language, a language derived from Dutch. The scientific name

*Orycteropus afer* is derived from Greek and can roughly be translated to “digger foot of Africa.”

### Description

Aardvarks have large bodies with elongated heads and very small necks. They are nocturnal animals that live in dug burrows and come out at night to forage for insects. Their snouts end in a flat nose that has small hairs to keep dirt and insects out of their nostrils. They are covered in coarse fur on most of their bodies except their tail and part of their head. They are naturally a yellowish-gray color but often appear brown or red due to their fur retaining soil from their burrowing activity. It is thought that fur in this mammal is not necessarily to help regulate temperature like with most mammals, but rather to help prevent ants and termites from biting their thick skin during their foraging forays. Due to being a nocturnal species, their skin can burn if they are in the sun for an extended period. This can be problematic for aardvarks kept in captivity, and zookeepers will frequently cover aardvarks in sunscreen to prevent sunburn. A difference that has been noted between male and female aardvarks is that females have lighter colored heads and the tip of the female's tail is white. While the purpose of this is unknown, it is theorized that it is to help an aardvark cub follow their mother.

Aardvarks are able to independently move their large cylinder-shaped ears and close their nostrils on demand when digging to prevent dirt and insects from entering their ears and nostrils. As is the case with most nocturnal vertebrates, aardvarks are color-blind and have poor vision and rely on their keen sense of hearing and smell to navigate their surroundings. An aardvark's teeth are very different from the teeth of most other animals and are not meant specifically for grinding or tearing (Brewer 2003). Their teeth are a unique cylinder shape that lacks a root or enamel. The tooth is made of multiple smaller cylinders that are fused together to create the individual teeth. Aardvarks use their highly adapted teeth to break the exoskeleton of the insects it licks with its tongue. One theory on the evolution of the unique shape of their teeth is that it is caused by a symbiotic relationship they

have developed with the aardvark cucumber. (*Cucumis humifructus*) (Knothig 2005). The cucumber is a subterranean fruit that gets its namesake from only animal known to dig them up and eat them – the aardvark. The seeds are then released in the feces, which the aardvark bury. Their large spoon-like claws are good for digging into the hard earth and breaking open cement-like termite mounds. An aardvark's tail acts as a weight to allow them to stand on their hind legs and grip an insect mound with their forelimbs. This standing position helps provide the grip necessary to break open hard termite mounds with their claws. Once an aardvark is fully grown, they are about 6 ft long (1.83 m) from snout to tail and can weigh between 80 and 150 pounds (36.29 kg and 68.04 kg, respectively) on average.

### Habitat

In the wild an aardvark's habitat consists mostly of open woodland, scrub, and grassland. They generally avoid dense forests, deserts, and mountainous terrain due to being ill-equipped to live in those areas. They prefer to burrow in areas where the soil is loose and easy to dig into and that is within a reasonable distance from their foraging area (Knothig 2005). Aardvarks can largely be found roaming throughout sub-Saharan Africa but are unevenly distributed due to ill-suited terrain and human interference. It is unclear if aardvarks are truly territorial due to lack of empirical studies and their solitary, nocturnal behavior. Some evidence shows aardvark will maintain multiple burrows over a large home range, sometimes even miles apart, each of which will have a specific purpose (Knothig 2005). Some dens may be used as a temporary resting place after a night of foraging forays, and others may exist only to be used for hiding from predators. Aardvarks also construct more permanent dens that are mainly used by females with cubs. However, they generally have several dens in several areas, as well as several tunnels, or tunnels that are made specifically to hide from predators within a home range. Aardvarks are primarily nomadic, with the main exception being for females caring for cubs, which generally stay in one area for safety of her

offspring. Their burrows can be quite large – as much as 10–13 m (33–43 ft) long – and generally have several entrances and chambers used for sleeping and rearing offspring. The burrows are built to retain moisture and regulate temperature, making it cool during the day and warm at night. Once aardvarks abandon a burrow to move to a new area, the abandoned burrow can provide an environmental service by trapping seeds of plants in the entrance area where they cannot be destroyed by other factors in the environment. Abandoned burrows also provide an important keystone habitat function for other animal species, some of which are on the International Union for the Conservation of Nature (IUCN) threatened species list (Whittington-Jones et al. 2011). An example of one such group of species would be pangolin (*Phataginus* spp.) in areas where ranges overlap. Services provided by aardvarks can also extend beyond occupation of abandoned burrows. Some species, such as the aardwolf (*Proteles cristata*) and the bat-eared fox (*Otocyon megalotis*), will take advantage of termite mounds opened by an aardvark to eat the stray termites in disturbed mounds.

### Diet

An aardvark's diet mainly consists of ants and termites but can include aardvark cucumber, beetles, and insect larvae. Throughout the year ants are their primary food source, but during the winter months they will switch to prey that is more readily available, such as termites and other insects due to lack of available ants in the environment. An aardvark is willing to walk 10–20 miles per night during foraging forays. They forage in a zigzag pattern until they detect and begin to follow signs of food (Melton 2008). Aardvarks capture their prey using a combination of their long prehensile tongue, their adhesive saliva, and large claws. All of these features together make the aardvark well-suited for accessing ant and termite mounds, some of which can be as hard as concrete. As they eat, their tongues also collect dirt and small rocks which help an aardvark to digest the insects it consumes. Aardvark disturbance at mounds

compounds with consecutive night forays. They will start disturbing the mound slowly, inflicting only minor damage; however, after several nights of consecutive visits, they can dig entirely into the ant and termite mounds such that their whole body can fit inside the hole they have created. In captivity an aardvark can be fed a mixture of fruits and vegetables, rice, vitamins, and several other ingredients to replace their natural diet. However, they can be difficult to care for in captivity due to their nocturnal nature as well as their dietary and habitat needs. For the food to be edible, it must be blended into a fluid consistency due to an aardvark's teeth not adapted for chewing solids.

### Vulnerabilities

Even though aardvarks are primarily nocturnal, they are still hunted by animals such as lions (*Panthera leo*), African leopards (*Panthera pardus pardus*), hyenas (*Hyaenidae*), and large snakes (mainly pythons). Warthogs (*Phacochoerus africanus*) have also been known to attack young aardvarks. Aardvarks are a very cautious and systematic animal. They will complete a specific series of events every time they prepare to leave their burrow. They spend substantial time listening for potential predators prior to departure from their burrow. If they unintentionally make noise that may attract the attention of predators, they will stop and listen again until perceived predation risk is diminished. This hypervigilant behavior continues within a few feet of their burrow such that they may bolt back to the burrow if necessary. Fleeing to a burrow is a primary means of defense in this species. Aardvarks digging unfinished burrows are more vulnerable as they are forced to exit their den backward and do not yet have appropriate escape cover. They also have been shown to use their powerful hind legs and large claws to ward off predators during agonistic interactions. The predominant danger to the aardvark's habitat and way of life is encroachment by humans. They are regularly killed by farmers for damaging roads, fences, and dams. Aardvarks are hunted for bushmeat and use in traditional medicine. Climate change poses a formidable risk to sustainability of aardvark populations as they may not be able to

adapt to minor changes in temperature and are at risk for reduced food availability if prey items are vulnerable to temperature changes.

### Life Cycle

Aardvarks have been known to live for about 20 years in captivity, but their life span in the wild is unknown. Aardvarks are solitary in nature and only come together during mating season where nomadic males will spend several weeks with a female mate before moving on in an attempt to find another female to mate with. Gestation for a female aardvark is about 7 months in duration, and they usually produce a single cub per pregnancy. Newborn cubs are small, pink, hairless, and blind and only weigh about 2 kg. An aardvark cub is almost entirely dependent on its mother during the first 2 weeks post-parturition. During this time the cubs use their hearing and sense of smell in order to navigate their environment. Cubs will remain in the burrow during that 2-week period before being able to venture out on short forays at night with their mother; however, they will not be weaned until approximately 3 months of age. Cubs will begin to create their own burrows just outside of their mother's burrow at about 6 months of age but will not completely leave their mother's burrow until around the time they are able to mate. They become capable of reproduction at about 2 years of age.

More facts about aardvarks:

- Much of the aardvark's fame is because it is the first animal to appear alphabetically in an English encyclopedia making it largely unknown in countries where English is not the primary language spoken.
- Aardvarks are commonly called anteaters, but they are not related at all. The reason for the incorrect comparison is due to both being myrmecophagous species, meaning they eat ants and termites primarily.
- Very little is known about aardvarks due to being reclusive in their natural habitat, and very few are found in captivity.
- Their powerful legs, feet, and claws are so strong they are able to shift about 2 ft of soil in about 15 s. That is more than a team of men with shovels can do.
- The aardvark is the only member of the order Tubulidentata, which is a reference to its unique tube-shaped teeth, that is known to still be alive at this point in time.
- In 1869 the first aardvark to be placed in a zoo was brought to London from South Africa (Goldman 2007).

## Absolute Number Discrimination

Krista Macpherson  
Department of Psychology, Western University,  
London, ON, Canada

Number plays a continuous role in humans' everyday interactions – for many, our early morning routine may involve checking the temperature outside to know whether to grab a jacket on our way out the door, or checking our pockets for correct change to grab a coffee. Likewise, number is also an important function for nonhuman animals in their daily existence – knowing how much food is available, how many offspring one has, or how many predators are approaching are all useful survival skills that may be assessed through the use of numerical discrimination.

Counting in humans is defined as a formal process of enumeration in which each item in an array must be given a unique tag (Piaget 1952). When counting is referred to colloquially in research with nonhuman animals, it is generally referring instead to simple numerical discrimination, as opposed to formal number systems or mathematical ability (the exception to this are studies which explicitly study whether animals are able to discriminate absolute discrete number; however, results from these studies as a whole are inconclusive). Arithmetic is the product of human language and culture, and is generally considered a uniquely human construct. Interestingly, however, two human tribes (the Pirahã and the Mundurukú)

have been shown to exist with no formal system or language to represent number (Everett et al. 2005; Sheffler 1978). The Mundurukú have number words up to only five, although each word is not as definite in meaning as number words in English; the Pirahã, on the other hand, do not have words for precise numbers, but rather concepts for small amounts versus larger amounts. Interestingly, in both cases, the lexical limitation is no obstacle to the ability of these individuals to discriminate between larger quantities of items (Gordon 2004; Pica et al. 2004). Likewise, preverbal human infants are able to discriminate quantities, despite lacking linguistic ability to express their choices (Wynn 1992; Xu and Spelke 2000).

Adult humans, nonhuman animals, and preverbal infants are all able to discriminate basic quantities due to an evolutionarily primitive system of numerical discrimination, known as the approximate number system (ANS; Merritt et al. 2012). According to the ANS, number is represented internally on a continuous number line, which allows both humans and nonhuman animals to discriminate approximate magnitudes. Number only takes on a discrete representation in human language when number symbols become mapped onto these approximate magnitudes through learning during childhood language acquisition and subsequent mathematics training. It is from this shared and primitive system that number symbols and the more precise use of number that is typical of adult humans has presumably risen.

A key element of the approximate number system is that it obeys Weber's law. Weber's law states that the change in stimulus intensity needed for an organism to detect a change is a constant proportion of the original stimulus intensity, rather than a constant amount. Two effects that are seen as a result of this are the *distance* effect and the *magnitude* effect. The distance effect maintains that the greater the distance between two numbers, the easier they will be to discriminate (for example, 9 vs. 1 will be easier to discriminate than 3 vs. 1). The magnitude effect is the common finding that when distance is held constant, larger numbers are harder to discriminate

than smaller numbers (for example, 2 vs. 1 is easier to discriminate than 9 vs. 8).

Ratio effects in accordance with Weber's law have clearly been demonstrated in many species. The most intensive early work in this area was conducted by Otto Köehler, with a variety of bird species (Köehler 1951). Subjects were presented with containers covered with lids showing different numbers of pieces of grain glued to the lid. The birds were rewarded for pecking at the lid with fewer pieces of grain, and punished for choosing an incorrect lid (punishment in this case ranged from being shooed away from the container by the experimenter, to having the incorrect lid thrown up into the air by a device known as the "frightening springboard" upon selection). Birds learned to choose the lid with fewer items; however, there are several alternate ways in which they could have solved this problem. If comparing, for example, a lid with 2 pieces of grain to a lid with 5 pieces of grain, the 2 pieces of grain will take up less space than the 5 pieces of grain, making it possible for the birds to solve this problem based on a judgment of surface area, rather than number. With enough trials, the birds could also simply learn to recognize the lid with two items as the correct response, without actually making a judgment based on relative numerosity. While it is not known if Köehler took any measures to eliminate these potential confounds, current studies of number in animals typically control for these issues by manipulating the size of stimuli such that it cannot be used as a reliable source of information. Animals are also typically trained with one set of ratios, and then tested with a new set of ratios. If an animal has simply memorized correct responses, then their performance should fall to chance when given new ratios. If, on the other hand, they understand numerosity they should apply the rule "choose the smaller number of items," making it possible for the animal to choose correctly when given a ratio they have never seen before (it is worth noting that Köehler taught animals to choose the smaller number of items, whereas most studies typically teach animals to choose the larger number of items).

Number has also been studied through the use of the operant conditioning chamber. Roberts

(2010) showed pigeons three different combinations of red and green light flashes, using ratios of 2 versus 1, 3 versus 2, and 4 versus 2. The use of these particular ratios was important because the distance between numbers is 1 for 2 versus 1 and 3 versus 2, but increases to 2 for 4 versus 2. The ratio between numbers, on the other hand, was equal for 2 versus 1 and 4 versus 2, but smaller for 3 versus 2. If distance was controlling the performance of the pigeons, then it should have been found that 4 versus 2 was most easily discriminated, while 2 versus 1 and 3 versus 2 were harder but equally discriminable. Instead, it was found that 2 versus 1 and 4 versus 2 were equally discriminable, while 3 versus 2 was significantly more difficult to discriminate. This finding suggests that ratio, not distance, was controlling the performance of the birds.

Number takes three forms – cardinal, ordinal, and nominal numbers. Cardinality refers to the elements of a set, and essentially asks the question "how many." Ordinality refers to the rank of an item (e.g., third place). Nominality concerns assigned numbers (e.g., zip codes in the United States) used for labeling purposes only, and is therefore a uniquely human practice. Studies of numerosity in nonhuman animals are thus concerned exclusively with cardinal and ordinal number. When animals choose between two discrete numbers (e.g., 2 vs. 4), this constitutes a study of cardinality. Ordinality, however, has also been assessed in nonhuman animals. In a landmark study, Brannon and Terrace (1998) trained two monkeys to respond to displays containing 1–4 items in an ascending numerical order. As a control for non-numerical cues, exemplars were varied with respect to size, shape, and color, such that the correct response could only reliably be obtained through the use of number. The monkeys were later tested, without reward, on their ability to order stimulus pairs composed of the novel displays of 5–9 items. Both monkeys were found to correctly order the novel items. In another study, Cantlon and Brannon (2006) trained monkeys to order pairs of numerical stimuli with the values of 1–9. Once the monkeys learned to order these values, they were introduced to pairs of novel displays of 10, 15,

20, and 30 items. Once again, monkeys were able to spontaneously order the novel values, suggesting that there is no known upper limit on the numerical capacity of these animals.

A number of different procedures have been used in studying number in nonhuman animals. Often, these paradigms have been borrowed from developmental psychology studies of human infants, as in both cases procedures need to be nonverbal. In one study (West and Young 2002), a version of the preferential looking technique that had previously been used with infants (Wynn 1992) and monkeys (Flombaum et al. 2005) was adapted for use with dogs. In this task, dogs watched as food items were placed, one at a time, behind a screen and out of their view. The screen was then lifted so that the dog could see the resulting number of items. In one condition, dogs saw a simple, correct calculation ( $1 + 1 = 2$ ). In two other conditions, however, dogs either saw an unexpected outcome in which fewer objects were present when the screen was lifted than should be expected ( $1 + 1 = 1$ ), or saw an outcome in which more objects resulted than should be expected ( $1 + 1 = 3$ ). When an expected outcome was used, dogs spent as much time looking at the outcome as they did looking at the initial presentation of items, but when a result was unexpected, dogs spent significantly longer looking at the resulting amount of food. This suggests that, like infants and monkeys, dogs may have been anticipating the outcome of the calculations, which would require them to employ some form of numerical system.

While the majority of numerical experiments with nonhuman animals take place in a laboratory setting (where arguments could be made that numerical ability is the result of thousands of trials in an artificial scenario), animals have also been shown to be sensitive to number in the wild. In one study using playback recordings of lioness roars, defending adult female lions were found to be more likely to approach the location of the recordings if they heard the roar of a single female lion, than if they heard the roars of three female lions (McComb et al. 1994). Avoiding the costs of engaging in territory fights with larger groups of assailants presents one of many selective

advantages presented by the use of numerical information in the wild.

There is substantial support for the existence of the ANS, meaning that numbers are represented internally in an indiscrete fashion on a number line. The mathematical formulation of this number line, however, has been debated. Some researchers (Whalen et al. 1999) have proposed that this number line uses scalar variability. In this case, the numbers on the number line are equally spread, with variability that increases across numbers, making discrimination more difficult. Proponents of the logarithmic model (Nieder and Dehaene 2009), on the other hand, maintain that variability is fixed, while numbers themselves are numerically compressed as magnitude increases across the number line. Predictions made by both of the models, however, are quite similar.

While the ANS remains the most dominant explanation for numerical processing, arguments have also been made for a secondary number system, often referred to as the object file system (Brannon 2006; Carey 1998; Feigenson et al. 2004). While the analogue magnitude system is generally an accepted account of numerical representation, the object file system is more controversial. The object file system (sometimes referred to as “subitizing”) deals only with small numbers, specifically numbers 1–4. These numbers are thought to be mapped discretely in a one-to-one representation, making them instantly accessible. For example, if subjects are shown four dots on a screen, they do not need to systematically count the dots because they will immediately recognize that there are four dots.

In support of the object file system, Hauser et al. (2000) found that wild, untrained monkeys were able to discriminate and successfully choose a larger number of food items over a smaller number of food items. Over 200 semi-free-ranging rhesus monkeys watched as experimenters placed pieces of apple into each of two containers. The experimenters then walked away so that the monkeys could approach the containers. When the containers contained ratios of 1 versus 2, 2 versus 3, 3 versus 4, or 3 versus 5 slices of apple, the monkeys chose the container

with the greater quantity of food. Interestingly, however, when the ratios exceeded the number four (4 vs. 5, 4 vs. 6, 4 vs. 8, or 3 vs. 8) the monkeys were unable to reliably choose the container with the most food. Hauser et al. suggested that the breakdown in performance of the monkeys when the number exceeded four items is evidence that the monkeys were using a spontaneous number system (i.e., the object file system) as opposed to an analogue magnitude system in order to solve the problem. In subsequent laboratory studies, (Beran 2001; Beran and Beran 2004), however, experiments analogous to those of Hauser et al. (2000) were conducted, in which chimps watched as an experimenter sequentially dropped pieces of food (M&Ms. or pieces of fruit), one-by-one, into each of two bowls. The chimp was then allowed to choose one of the two bowls and consume its contents. In this laboratory task, chimps discriminated magnitude well beyond 4 items, and up to 10 items.

The most persuasive argument against the use of an object file system is that even with numbers 1–4, both humans and nonhuman animals have been shown to demonstrate the ratio-effects that are the signature of the ANS (Beran and Rumbaugh 2001). If the one-to-one representation suggested by the object file system were in fact being used, then these ratio effects should not be seen for the numbers 1–4. As a result, some researchers question the evolutionary need for this secondary system. An alternate explanation for the extremely rapid processing of numbers 1–4 would be that the ANS is simply very quick in discriminating such small quantities, because of their lesser magnitude.

Rapid advances in the development of functional magnetic resonance imaging (fMRI) technology has provided further insight into the understanding of numerical cognition, implicating the intraparietal sulcus (IPS) as the primary brain structure involved in numerical processing (Nieder 2005). Although it was originally thought that the IPS might contain a specified number module, evidence now suggests that the IPS serves a “patchwork” of different functions (Ansari 2008). The prefrontal cortex (PFC) is also involved in numerical processing; however,

response latencies are faster in the IPS than in the PFC, suggesting that the IPS extracts numerical information and subsequently sends the information to the PFC for processing (Nieder and Dehaene 2009).

Single cell recordings have also proven to be a great asset in understanding numerical processing. In a delayed matching to sample task (Nieder and Miller 2004), monkeys were shown an array of 1–5 items and subsequently had to decide if a sample array matched this number. Single-cell recordings showed that the monkeys had number-selective neurons, which fired preferentially to particular numerical values and thus appeared to be “tuned” for specific numbers. These tuning curves are imprecise, such that a neuron with a “preference” for 6 may also fire for 5 and 7. The resulting tuning curves help explain the distance and magnitude effects associated with the analogue magnitude system. When two numbers are farther apart, their respective tuning curves will overlap less, creating less “noise” around the number and making them easier to discriminate. Tuning curves, however, get wider and less precise as numerical magnitude increases. Thus, while 1 versus 2 will have narrower tuning curves that are more precise, 8 versus 9 will have broader tuning curves that overlap more with surrounding numbers, making discrimination more difficult.

The question of numerical processing in animals can be traced back as far as the misadventures of Clever Hans (Pfungst 1911). While it was proven that Hans was not able to perform any type of arithmetic, we know today through the comparative study of number that many nonhuman species are sensitive to numerosity, and can make decisions based on this information. Advances in technology through the use of both fMRI and single cell recordings have also thoroughly increased our understanding of numerical processing, allowing researchers not only to pinpoint regions of the brain associated with number, but also to identify number selective neurons, which elegantly explain behavioral data in terms of Weber’s law and the ANS. To date, there is little information as to what the upper limit of numbers that can be discriminated may be in nonhuman

animals. Additionally, further comparative investigation may be useful in understanding species-related differences in numerical discrimination, and how they may be related to memory systems. For example, although both chimps and monkeys have been successful in numerical tasks with sequential presentation of items (Beran 2001; Beran and Beran 2004), there is evidence that monkeys more easily discriminate numerosity in tasks that use simultaneous presentation of items (Nieder et al. 2006). Furthermore, in a study with dogs (Macpherson and Roberts 2013), subjects were found to be incapable of discriminating number in several variations of a sequential task, yet discriminated number easily when stimuli were presented simultaneously. This apparent difficulty in discriminating sequentially presented items may reflect a limitation in working memory, as subjects in these experiments must mentally keep track of how many items they have seen presented to them. Further studies are needed to more fully understand any cognitive or physiological differences in processing number across species.

## Absolute Pitch

Stephen C. Van Hedger and Howard C. Nusbaum  
Department of Psychology, The University of  
Chicago, Chicago, IL, USA

## Synonyms

[Perfect pitch](#)

## Definition

In humans, the ability to name or vocally produce any musical note without using a reference note. More broadly, the ability to accurately remember auditory pitch not just in terms of the relationships among pitches.

## Introduction

If you ask a musician for an example of a musical talent or gift, one of the most common answers would be absolute pitch (AP), and for good reason. Typically defined as the ability to name or produce musical notes without the need for a

starting reference, AP is thought to be exceedingly rare, with an estimated incidence of occurrence of around 1 in 10,000 people (Bachem 1955). While this number may vary substantially across cultures (Miyazaki et al. 2012), it is clear that AP is disproportionately present in top music conservatories across the world (cf. Deutsch et al. 2006), and moreover, a number of well-known composers and musicians, from Mozart to Mariah Carey, have reportedly possessed AP. Yet, despite over a century of empirical research, the origins and nature of AP are still an open scientific question, situated within a broader question about the origin and nature of listening skills and expertise.

## The Etiology of AP

Perhaps the most fundamental debate in the study of AP is how the ability develops. An influential theory of AP development is the *critical period theory*, which posits that AP depends entirely on musical training acquired early in life, during a critical period of development. A number of studies have reported that AP and early musical training are associated, assessed both by self-report (Bachem 1940; Levitin and Rogers 2005; Vitouch 2003) and tests of pitch identification (Deutsch et al. 2006; Lee and Lee 2011). Other early-life experiences that affect attention to pitch and that covary with AP, such as tonal language experience (e.g., Mandarin Chinese, Deutsch et al. 2004) and congenital or early-onset blindness (Hamilton et al. 2004), have also been used to support the *critical period* theory. Recently, the *critical period theory* was supported by a study demonstrating that a drug treatment, thought to “reopen” the critical period in mice (Yang et al. 2012), potentiates acquisition of AP in adult human listeners (Gervain et al. 2013), although in this study, AP performance was well below the performance that is criterial of AP listeners.

The *genetic theory* of AP asserts that development depends on a specific genetic endowment, requiring relatively minimal environmental shaping. The fact that AP tends to run in families supports this (Theusch et al. 2009), but it is difficult to differentiate genetic from environmental

factors, given that early musical training also runs in families (Baharloo et al. 2000). The rate of AP concordance among identical twins is significantly higher than the rate among fraternal twins (Theusch and Gitschier 2011). However, the “equal environment assumption” of twin studies may not be tenable, as identical twins tend to be treated as more similar than fraternal twins (Joseph 2002). Overall, despite several investigations, the putative genes for AP have not been identified, and it is clear that if there is a genetic basis to AP, it is not inherited in simple Mendelian fashion (Theusch and Gitschier 2011).

Given there has been some support for both the *critical period* and *genetic theories*, a third theory integrates these in a *hybrid theory* (Zatorre 2003). This *hybrid theory* states that early musical training within a critical period is necessary, but not sufficient, for AP to develop. Rather, early musical training must be accompanied by some genetic predisposition.

The *practice theory* conceptualizes AP as a listening skill, able to be learned at any time in life through perceptual training along with the appropriate general cognitive mechanisms for effective learning (e.g., effective attention control, sufficient working memory). Until recently, this theory has not been considered seriously because prior AP training studies have produced only modest improvements in absolute pitch identification (Takeuchi and Hulse 1993), and retention of this modest learning has been assumed to be short-term, although it has not been generally tested after a substantial retention interval. But there have been some studies that reported pitch identification performance comparable to “genuine” AP possessors after training (Rush 1989), with trained performance persisting for several months (Brady 1970). More recently, adult training of AP was shown to be statistically associated with individual differences in auditory working memory, which actually mediated the relationship between early musical training and AP learning in adults (Van Hedger et al. 2015a). These findings suggest that AP acquisition in adults may be better understood as a listening skill rather than an ability endowed at birth or crystallized within a critical period. This treats the skill of AP as

similar to other perceptual skills, given that working memory has been implicated in a variety of other perceptual category-learning tasks (Lewandowsky et al. 2012).

## Describing AP

Many of the controversies surrounding the origins of AP could be seen as rooted in a simple question that has no simple answer: *How should AP be measured?* The conventional definition (being able to name or produce a musical note without the aid of a reference note) is broad and does not address issues that arise when considering the actual variability in AP performance based on a number of factors, some of which are outlined below. This variability is important because, contrary to the simple definition, systematic and idiosyncratic variability in AP performance suggests the conception of the process of AP is neither monolithic nor exactly the same across people or time, which has implications for understanding how AP arises and operates.

**Variability in Note Identification:** The instrumental timbre and octave register of the to-be-identified note can influence categorization accuracy (Bahr et al. 2005). Individuals tend to have better AP memory for their primary instruments, sometimes to such an extent that AP ability does not manifest for other instruments (Ward and Burns 1982). There are also systematic differences in AP accuracy based on instrumental timbre, as timbres such as pure tones (Lockhead and Byrd 1981) and the human voice (Vanzella and Schellenberg 2010) tend to be harder to identify compared to timbres such as piano and violin. Even among highly familiar instrumental timbres and octave registers, AP possessors display reduced performance when making judgments about notes that randomly switch between timbre and octave, suggesting that these attributes are an integral part of their category representations (Van Hedger et al. 2015b). Given that many tests of AP ability only present participants with one or two timbres (e.g., Athos et al. 2007), results of many AP assessments may not fully capture the diversity of AP.

Particular notes may also relate to difficulty of AP categorization. Specifically, “black-key” notes tend to be less accurately and more slowly identified compared to “white-key notes,” with the notes “C” and “G” being easiest to identify (Miyazaki 1990). While this effect was initially described using a critical period framework – as white keys are generally learned at the youngest age and before black keys on a keyboard – the current prevailing view is that these note class differences stem from distributional differences in the listening environment. For example, Deutsch et al. (2011) were able to explain about 65% of the variance in note categorization accuracy with the estimated frequency of occurrence of each note in the listening environment.

The listening environment also appears to be essential in holding note categories in place. Both past and present environmental factors are important in the development and maintenance of AP (Wilson et al. 2012), with recent musical activity able to “tune up” AP ability (Dohn et al. 2014). Moreover, the “present” environment can be operationalized at a rapid timescale – within a single experimental session. When presented with music that was flattened by a fraction of a semitone, AP possessors reoriented their sense of what is “in tune” versus “out of tune” based on this listening experience (Hedger et al. 2013; Van Hedger et al. 2018).

On top of environmental influences, AP ability has been documented to shift with age, though the mechanisms for this change are not well understood. These age-related shifts have been reported as early as 40 years old and can progress to the point where individuals are two or three semitones removed from the “correct” note (Ward 1999). However, some individuals demonstrate no age-related shift, and thus more work is needed to understand the physiological and cognitive components of this effect. Given that these shifts would result in an individual consistently misclassifying a note by a fixed amount, some researchers have given partial or full credit for semitone errors (e.g., Athos et al. 2007) or assessed AP ability by the relative deviation of a

response to the “correct” answer (e.g., Bermudez and Zatorre 2009).

AP as Dichotomous Versus Continuous: By this point, it should be clear that an individual’s past and present experiences indelibly shape their AP “fingerprint,” and thus AP is not synonymous with the perfect identification of any pitched sound. This variability in AP identification, however, means that the empirical study of AP requires establishing performance thresholds that can appropriately differentiate “AP possessors” from “non-AP possessors.” Yet, the question of whether individuals can be cleanly binned into categories of “AP possessor” and “non-AP possessor” has been controversial since the earliest days of empirical research on the topic (Bachem 1937).

Support for AP as a dichotomous versus continuous ability appears to depend on the way in which it is tested. Often, tests of AP involve making a *timed* note category judgment (generally within 3–5 s). The logic for this “timeout window” is that AP should involve the *rapid* identification of a pitched sound. Indeed, when adopting this testing format, performance appears to be binned into relatively discrete populations of individuals near chance versus individuals near ceiling accuracy (Athos et al. 2007). However, allowing for longer periods to respond can reveal a more variable distribution, with many individuals falling between chance and ceiling performance (Bermudez and Zatorre 2009). As such, timed tests may exaggerate the dichotomous nature of AP.

Another factor in the consideration of AP as dichotomous versus continuous is that of *implicit absolute pitch*. While implicit AP is measured in several ways, the fundamental idea is that most individuals, regardless of explicit AP or musical training, have some long-term memory for absolute pitch based on pitch regularities in the listening environment, even if they are not able to assign cultural labels (e.g., note names) to isolated pitches. For example, individuals can differentiate popular melodies (Schellenberg and Trehub 2003), single iconic pitches such as the censer “bleep” (Van Hedger et al. 2016b), and even

isolated in-tune from out-of-tune notes (Van Hedger et al. 2016a) based on absolute pitch information. These examples illustrate that the listening environment shapes long-term memory for absolute pitch across *all* individuals, not just those who can explicitly label isolated notes.

AP in Nonhuman Animals: When conceptualizing absolute pitch in broader terms – not tied to associating pitches with culturally specific labels – it becomes possible to discuss how absolute pitch manifests in nonhuman animals. For example, in an operant conditioning paradigm that has been used across species, listeners are rewarded for responding to some ranges of tones but not others, and moreover the rewarded tone ranges are interleaved with the non-rewarded tone ranges (Weisman et al. 2012). In this paradigm, most rats (*Rattus norvegicus*) and humans showed successful learning with three, but not eight, tone ranges. In contrast, pigeons demonstrate some success at the eight tone-range task, and many vocal-learning birds displayed high levels of accuracy on both three and eight tone-range tasks (Friedrich et al. 2007). From these results, it is perhaps tempting to conclude that avian species – in particular, vocal-learning avian species – have better absolute pitch abilities than mammals. However, it should be noted that humans with absolute pitch are able to perform at levels that approach vocal-learning birds, though their pattern of errors suggests that they potentially engage in different strategies (Weisman et al. 2010). Overall, comparative work is valuable for understanding the nature of absolute pitch abilities across species, though it is important to consider how absolute pitch is operationalized before claiming that particular species do or do not “possess” absolute pitch.

## Conclusion

Absolute pitch has fascinated musicians, scholars, and the general population since it was first formally described, largely because of its conceptualization as a rare and mysterious expertise. In part, this idea of AP has been bolstered by

oversimplifying the description of AP, and not considering just how much variability exists in AP performance across and within listeners. While there are still many unanswered questions surrounding its development, it has become clear that AP is best conceptualized as a kind of listening expertise rather than an endowed special ability. Moreover, given that implicit, long-term memory for absolute pitch appears to be present in almost everyone, as well as several nonhuman animal species, it is possible that what makes AP special is the learning by which listeners develop the musical knowledge to understand and categorize absolute pitch in the context of a culturally developed system of music.

## Accidental/Intentional Experiment

Mary K. Radeke

Central Washington University, Ellensburg, WA, USA

### Synonyms

[Intentionality test](#); [Theory of mind](#); [Unintentional and intentional experiment](#)

### Definition and Description

An experiment in which subject responses to purposeful (intentional) and unplanned (accidental) actions by an experimenter are measured as a means to identify whether an individual (human or nonhuman) understands the intentional actions of others. The intentional and accidental experiment is relevant to the topic of theory of mind, as it tests whether subjects understand intentional behaviors, one of the requisite components to understanding that others have thoughts and beliefs similar or separate to their own.

Two common variations of the accidental/intentional experiment use “accidental” and “intentional” actions of experimenters while indicating the location of rewards and “clumsy” and “competent” experimenters responsible for delivery of rewards. The basic premise of the experiment is that the subject must discriminate between the actions of the experimenter that will result in successful delivery of the reward and those that will not result in delivery of the reward.

In an initial study, subjects were trained to identify or request an item (usually food reward) hidden under an opaque container that has been identified with a marker placed on top of it, signaling the location of the food (Call and Tomasello 1998). During the subsequent testing phase, the marker was either intentionally placed on top of the container or accidentally dropped onto one of the other containers. In this procedure, the container was said to have been marked intentionally or

accidentally. The subject was presumed to have recognized the intentions of others if the intentionally marked container was selected over the accidentally marked container (Call and Tomasello 1998).

In another variation of the task developed by Povinelli et al. (1998), during the training phase, subjects were exposed to a “clumsy” experimenter who accidentally dropped the reward, a “competent” experimenter who successfully delivered the reward, and a “negligent” (and in some cases “aggressive”) experimenter who intentionally dropped the reward. During the subsequent testing phase, the subject was to be given the chance to select the reward from one of the three experimenters. In this procedure, the subject was said to have recognized the intentions of others if the “competent” experimenter was selected over the “clumsy” and “negligent” experimenters (Povinelli et al. 1998).

In the intentional and accidental action experiment, the actions are often signaled by experimenters with eye gaze (toward or away from a location), intentional or accidental dropping or misplacing of the food reward, failure to deliver a food reward, and verbal cues such as “oops,” “oh no,” “okay,” and “there.”

## Human Studies

Research on the ability of children to recognize intentions has primarily focused on young children, and the comparative framework for comparing humans and nonhumans involves studies with young, preverbal children (infant to 2 years). In these studies, researchers have relied on nonverbal measures such as eye gaze (Phillips et al. 1992), habituation-dishabituation (head turn) (Gergely et al. 1995), imitation (Meltzoff 1995; Carpenter et al. 1998; Olineck and Poulin-Dubois 2005), and reaching/grabbing (Behne et al. 2005) in order to identify whether or not children are able to recognize the intentions of others. Research using each of these measures suggests that by the end of their first year, children are able to identify the intentions of others.

Many of the studies that examine the ability of children to recognize intention and accidental actions incorporate verbal indicators or cues to signal the intentional and accidental actions. For example, Carpenter et al. (1998; replicated by Olineck and Poulin-Dubois 2005) examined the ability of young children (14–18 months) to reproduce or imitate intentional and accidental actions modeled by an adult. These actions were indicated by the experimenter as intentional or accidental with the words “there!” (intentional action) and “woops!” (accidental action). Research using verbal cues to signal intentional and accidental actions indicates that young children, 16–18 months of age, imitated significantly more intentional than accidental actions modeled by an adult. Additionally, in studies that require the child to imitate an adult model as a measure of understanding, the intentional and accidental actions were signaled by the modeler/experimenter by failing to complete the task, negative facial expression (frown), dropping the object, or refusing to offer the object to the child (Meltzoff 1995; Behne et al. 2005). Results of these studies indicate that children as young as 9 months of age are able to differentiate the intention of others by observing the modeler/experimenter’s actions and facial expression (Behne et al. 2005).

## Nonhuman Studies

The bulk of research employing the use of intentional and accidental experiment methodology to test intentionality is found in research with primates, specifically the great apes. Two examples from research on chimpanzees and orangutans are presented below.

Call and Tomasello (1998) investigated the ability of human children, chimpanzees (*Pan troglodytes*), and orangutans (*Pongo pygmaeus*) to identify the intentions of others. The procedures for eliciting responses to intentional and accidental behaviors of the models consisted of a training and a testing phase. In the training phase, the authors trained the subjects to select a “correct” box containing a food reward using a three-phase delayed stimulus discrimination task. Phase one

consisted of introducing the subjects to the concept that a food reward could be found under one of the three boxes. Training subjects included partially hiding the food reward under the boxes. Visibility of the food rewards was slowly decreased on each subsequent trial until fully hidden. Phase two consisted of the introduction of a marker that “marked” the box containing the food (stimulus discrimination phase). In this phase, the subject was trained to select the box with the marker in order to obtain the hidden food reward within. The subjects learned to associate the marked box with the location of the food reward. Phase three consisted of a delayed-response procedure. In this phase, the marker was placed on the box containing the food reward but was then removed. The subject was then allowed to select the box with the food reward after a delay. Responses of the subject were delayed 1 s, increasing in successive trials to 10 s and then to 20 s (delayed discrimination task).

During the testing phase, the experimenter baited the boxes out of view of the subjects and then allowed the subjects to view the boxes without the presence of the markers. Two intentional actions and two accidental actions were then performed. The order of the presentation of the intentional and accidental actions, as well as the location of the hidden food, was counterbalanced. The two intentional actions consisted of (1) the experimenter picking up the marker and placing it on the top of the box while looking at the box and (2) the experimenter picking up the marker and dropping it on the box while looking at the box. In both intentional action types, the marker was left on the box for 3 s and was then removed. The boxes were then pushed toward the subject to allow the subject to select the box containing the food reward.

The two accidental actions consisted of placing the marker on a ledge behind the boxes and (1) the experimenter moving the ledge resulting in the marker being dislodged and falling on to one of the boxes and (2) the experimenter knocking the marker off of the ledge on to the box. While performing the accidental actions, the experimenter did not look at the boxes. After the accidental placement of the marker, the experimenter left the marker in place for 3 s, then removed the

marker, and allowed the subjects to select the box containing the food reward. A verbal prompt “oops” was used for two of the chimpanzee subjects in order to investigate the potential benefit of a verbal prompt on performance. Each trial consisted of one intentional action and one accidental action. The intentional and accidental placement of the marker may or may not have corresponded to the correct location of the reward. In other words, the marker may or may not have signaled the actual location of the reward. The authors hypothesized that when presented with the choice of these two marked locations, the intentionally marked location should be selected over the unintentionally or accidentally marked location, indicating the individual understands the intention of the experimenter. The subjects (both chimpanzees and orangutans) tended to select the intentionally marked boxes more than the accidentally marked boxes at the beginning of the experiment, and subsequently accuracy of their selections decreased as the experiment progressed. With regard to the decreased accuracy, the authors concluded that “...[this] could be interpreted as an indication that accidental actions became less plausible after accidents occurred in each trial” (Call and Tomasello 1998, p. 202).

Povinelli et al. (1998) used a procedure in which young chimpanzees were trained to point to unfamiliar actors in order to receive rewards (cups of juice). During the training phase of this experiment, the subjects were exposed to actors who handed cups of juice to experimenters who then offered the juice to the chimpanzees. The chimpanzees were then presented with actors who (1) “accidentally” dropped the juice on the floor before handing it to the experimenter, (2) “intentionally” poured the juice on the floor, or (3) “aggressively” threw the juice on the floor. The chimpanzees were then tested to see which actor they selected for delivery of the juice as indicated by pointing to the actors. The authors hypothesized that the actors who accidentally dropped the juice on the floor should be selected over those who intentionally or aggressively dropped the juice. The results showed nonsignificant effects of the three conditions, indicating that the chimpanzees did not show a preference

for which actor delivered the juice, leading the authors to conclude that chimpanzees are not able to tell the difference between intentional and accidental actions of human experimenters (Povinelli et al. 1998, p. 215).

In a second experiment, Povinelli et al. (1998) addressed some methodological issues such as the possibility that the chimpanzees preferred interacting with certain human actors over others. In this experiment, the actors were counterbalanced across three conditions for each chimpanzee; the same actors played one of the three roles for the same chimpanzee but switched roles for different chimpanzees. In this experiment, a neutral actor, victim actor, and intentional actor were used to deliver (or not deliver) a food reward. Each session contained two combinations of actor scenarios. The neutral actor picked up the food reward and handed it to the experimenter who then handed it to the chimpanzee. The victim actor delivered the food reward to the experimenter who then ate the food reward intended for the chimpanzee. The intentional actor always ate the food reward intended for the chimpanzee rather than handing it to the experimenter. After a training session in which the chimpanzees were exposed to each actor multiple times, counterbalancing for action and location (left or right side), the chimpanzees were tested for preference of human actors by exposing the chimpanzees to combinations of actors as (1) intentional actor versus victim, (2) victim versus neutral actor, and (3) intentional actor versus neutral actor. Results indicated that the chimpanzees did not prefer one actor over another, regardless of their behavior toward the experimenter. Similar to the first experiment by Povinelli et al. (1998), results from this modified procedure indicated that chimpanzees do not recognize the intentions of human experimenters.

## Limitations

As suggested by Call and Tomasello (1998), the accidental and intentional action studies used with nonhuman subjects may allow us to investigate whether nonhumans are able to differentiate between the subtle behavioral (and in some cases

verbal) cues that accompany intentional and accidental actions made by humans. However, just as errors occur in the ability to recognize intentional or accidental acts in human-to-human interaction (e.g., sarcasm, deception, threats, displays of emotion, etc.), we would also expect similar errors in nonhuman subjects, and, similarly, failure should not necessarily be an indication of inability.

Other limitations suggested by Povinelli et al. (1998) point to the developmental stage of the subjects tested. In their study, the chimpanzees (5–7 years old) were unable to distinguish between the accidental and intentional acts presented by the unfamiliar actors. Povinelli et al. suggest that this may have been due to the lack of cognitive development of their subjects. The authors also suggest that their subjects may not have perceived the difference between the types of actions “. . .because the severity of the outcome was too mild” (p. 215). Povinelli et al. seem to suggest that the consequences of the actor’s actions were of little significance to the subjects possibly due to the low or diminished value of the food reward.

Perhaps the most obvious limitation of the accidental and intentional action experiment is the use of linguistic cues employed by many researchers. Exclamations of “whoops” to indicate accidental action or “okay” to indicate intentional action may carry little to no meaning for the nonhuman subjects in these experiments. Call and Tomasello (1998) found that the two nonhuman subjects that were exposed to verbal cues did not performed any better than did subjects that were not exposed to verbal cues. Whether or not an individual recognizes an exclamation of “whoops” or “okay” to indicate accident or intention, the linguistic cue may simply serve to draw the attention of the subject to a desired reward, resulting in negative results. For example, inadvertently dropping a delicious treat on the floor may, for many test subjects in a laboratory environment, signal a rare opportunity for acquiring the delicious treat regardless of the intention of the actor. The verbal cues used to indicate accident or intention simply indicate the availability of the food reward.

Consideration must be given to the early rearing environment and the role this may play in the ability to understand the accidental or intentional acts of others. Call and Tomasello found that the orangutan Chantek performed much better than the other subjects in their study of accidental and intentional actions. Chantek's early rearing experience resembled that of a young child from the age of 9 months to 9 years. Chantek acquired the signs of American Sign Language and spent most of his waking hours with human caregivers (Miles 1986). Call and Tomasello attributed Chantek's superior performance to these early rearing experiences and human enculturation. In addition to the individual's environment, knowledge of the materials used in these tests as well as the familiarity of the animals to the experimenter/caregivers may yield contradictory results (although see Pitman and Shumaker 2009, refuting differences in early rearing conditions).

The social behavior of the different primate species tested must also be taken into account when assessing the ability to recognize the intentions of others. For example animals in the wild likely reap the rewards brought about by the actions of others, regardless of the intention of the act. The inadvertent (or possibly intentional) dropping of a highly coveted food item by a dominant individual may be recovered by a subordinate individual. Knowledge of whether the dominant individual meant to drop the food item may be irrelevant, if even knowable; the opportunity to recover the food and avoidance of repercussion from the dominant individual are paramount and perhaps necessary for survival. Another example of the behavioral differences between human and nonhuman primates was suggested by Call and Tomasello (1998). The authors stated that the type of action that resulted in the subjects selecting the location of the hidden food reward was the dropping of the marker on the box and not the intentional placement of the marker on the box. The authors hypothesized that the subjects identified this action (dropping) as an indicator of the hidden food reward because this pattern of behavior is more common (dropping of food) in

chimpanzees and orangutans than actual sharing of food by handing food or placing of food in another's hand.

Although the results of the accidental and intentional experiment may yield contrasting results across, and in some cases within, human and nonhuman populations with regard to evidence of theory of mind, the experimental procedure provides some insight into the cognitive capacities of these species. Age, social behavior, and methodological considerations however must be considered when comparing populations and making conclusions regarding the capacity to identify the intentional and accidental actions of others.

## Accipiters

Molly Chamblee<sup>1</sup> and Kristine O. Evans<sup>2</sup>

<sup>1</sup>School of Human Sciences, Mississippi State University, Mississippi State, MS, USA

<sup>2</sup>Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

## Synonyms

[Accipitridae](#); [Goshawk](#); [Hawk](#); [Sparrowhawk](#); [True hawks](#)

## Definition

A genus of the Family Accipitridae considered to be “true” hawks including 48 different species, many of which are goshawks and “sparrowhawks.”

## Introduction

Accipiters, or “true” hawks, have a variety of characteristics that separate them from other genera within the Family Accipitridae. There are 48 different species within the genus and include Cooper’s hawks (*Accipiter cooperii*), Sharp-shinned hawks (*Accipiter striatus*), Northern

goshawks (*Accipiter gentilis*), Eurasian sparrowhawks (*Accipiter nisus*), and many others. Though empirical studies of Accipiter hawks are limited, previous research has shown fascinating morphological and behavioral characteristics that maximize survival and fitness in this group of species.

## Habitat and Populations of Accipiters

The three common Accipiters of North America include Northern Goshawks, Cooper’s hawks, and Sharp-shinned hawks. Northern Goshawks are listed by the US Department of Agriculture Forest Service as a “sensitive species” and a “management indicator” due to their acute sensitivity to changes in their environment (Lawler and Schumaker 2004). Accipiters typically inhabit mature, closed-canopy forested areas but can be found in riparian areas, open landscapes, or isolated clumps of trees as well. These hawks prefer stands of trees with higher canopy volume and structure, and/or tree height variations.

Though Accipiter habitats can be affected by wildfires, timber harvest, and diseases, they are most drastically affected by urbanization. While many Accipiters are found in unaltered or “natural” habitats, they also occupy suburban and urban areas throughout North America. Landscape change due to urbanization alters the composition of bird communities; however, it is uncertain the degree to which the urban footprint is harmful or beneficial to Accipiter hawk species.

## Color Morphs and Sexual Dimorphism

Many raptors come in different morphs, or colorations. Plumage polymorphism is defined as variation in feather plumage coloration within the same age or sex of a population. This polymorphism is rare across avian taxa, and only occurs in around 3.5% of bird species. Within Accipiter species plumage polymorphism is typically exhibited by a dark morph and a light morph; however, frequency of polymorphism in a population may represent a response to environmental

circumstances or founder effect (i.e., reduced genetic diversity in a population due to a small number of ancestors) (Amar et al. 2013). Many Accipiter hawks also follow a unique form of sexual dimorphism: females are generally around 40% larger than males in most species. There are many hypotheses that have been proposed to explain the difference in size from hunting behaviors to female dominance in the species, but a definitive explanation has not yet been confirmed.

## Migration Behavior and Flight

Many Accipiters are considered migratory species. Cooper's hawks in California can be migratory or nonmigratory based on their geographic location, with populations in northern California exhibiting migratory behavior, and southern California populations exhibiting year-round residency (Bloom et al. 2017). This is assumed to be the effect of different climates and overwintering conditions across the migration range of these Accipiter populations.

Flight behavior in hawks is significantly affected by weather conditions during migration. Wind direction is the most significant driver in the flight height of migrating Accipiters. For example, Sharp-shinned hawks at Cape May, New Jersey, will fly lower in western winds, presumably to avoid being displaced over the Atlantic Ocean (Woltmann and Cimprich 2003). Alternatively, hawks have been shown to fly at higher altitudes in winds that are blowing in the direction of migration.

Accipiters also stagger migration initiation based on age and sex. First-year or younger birds precede adults by an average of 2 weeks, whereas females precede males by 1 week on average. However, there is evidence that some Accipiter species are shifting timing of migration compared to previous years, presumably due to increasing global temperatures. Autumn migration departures in sharp-shinned hawks are around 4 days later now than those in 1974 (Rosenfield et al. 2011). This could indicate climate change creating warmer, more-ideal environments for prey species.

## Pair Bonds

Many Accipiter species are thought to have ephemeral pair bonds – or bonds that are formed and only last through the breeding season. Female Accipiters usually have a larger home range than their male counterparts because males are the territory holders and more restricted in their movements than females. Females typically desert their breeding territories (which includes their mate), but males retain their breeding territory year-round. This separation among males and females results from limited resources in the breeding territory during the nonbreeding period. However, Accipiters of both sexes tend to remain year-round in urbanized areas, because of increased resource availability. For example, Cooper's Hawks in Tucson, Arizona maintained pair bonds outside of their breeding season creating perennial pair bonds (Boggie et al. 2015). This year-round interaction with a mate increases nest site defense, may prevent loss of a breeding site to competitors, and may solidify a mating-pair bond which could strengthen their partnership and improve breeding efficiency.

## Nesting

Accipiter nests can typically be found in large, tall trees in areas with limited groundcover. Nests built by raptors tend to be very large in comparison to the body size of the builder, with larger nests at reduced risk of damage or loss during weather events. For example, goshawk nests may reach more than 600 kg compared to their body weights of only around 1 kg. Nest size is not only affected by the size of the Accipiter species that built it but also environmental factors and age. Many Accipiters refurbish their old nests, year after year; however, this does not necessarily contribute to increases in nest size over time due to compaction. Larger nests can also indicate a greater number of eggs laid in a clutch and may improve reproductive success of an individual. Temperature – and, in turn, climate change – can affect nest size (warmer weather equates to a decrease in nest size). Nest size also correlates

with age of the individual and will begin to decrease as the bird begins to age. Thus, nest size is not only an indicator of clutch size but also builder condition (i.e., age) and potentially effects of climate change (Møller and Nielsen 2015).

Males will also build nests periodically. The purpose of these alternative nests is unclear, but it is inferred that these structures could be displayed for mate attraction and allow males to prepare a quality nest for a future reproductive year. A male Cooper's Hawk was observed in Oshkosh, Wisconsin, building a nest in the absence of a female mate; however, that nest was utilized later that year for a clutch of eggs (Rosenfield and Sobolik 2017).

### Food Delivery and Brood Maturation

In most Accipiter species, the female incubates her brood while the male hunts and delivers food to the nest. Once the nestlings become more independent, the female will usually resume hunting to help the male in provisioning food. While these delivery methods and contributions may differ slightly between individual species, males typically exhibit greater food delivery rates, up to 80% of deliveries on average (Eldegard et al. 2003).

Accipiter nestlings spend around 40 days in the nest. Eurasian Sparrowhawks specifically have a 4-week nesting period, followed by a fledgling period that lasts around 3–4 weeks. Fledglings are dependent upon food delivery for a period of time after fledging and can depend on food provisioning from parents for weeks or months.

During the nesting period, the female rarely leaves the nest, except to retrieve food deliveries from the male. The female responds to male vocalizations during prey deliveries with a wail, and then she flies out to meet him and to retrieve the food. Direct nest deliveries by males are uncommon. It is believed that the female's wail may mimic that of the begging behavior in nestlings, which may encourage males to find and deliver more food.

A new behavior recently recorded by Rosenfield (2014) shows fledgling Cooper's hawks "proning." This activity notes that flighted fledglings will lie with their bodies flat against tree limbs or even on the ground. The purpose of this fledgling behavior is unknown, but some have hypothesized that it could be a variation of camouflage to help hide young birds as they continue to develop their flying skills and move further from their nest. This activity has been recorded across North America and is not specific to one individual group of Accipiters.

### Predation Behavior

Accipiter species all feed on different forms of prey, and prey preferences are driven by body size, location, and other factors. Eurasian sparrowhawks have been recorded to prey on over 120 bird species. Some Accipiters will even feed on other Accipiters; for example, goshawks have been known to prey upon the smaller sparrowhawks. While avian species provide the most biomass of most Accipiter diets, many – like Cooper's hawks – are opportunistic predators. They can feed on a variety of birds, mammals, and even lizards; but typically size of prey is relative to the raptor's body size.

Though often opportunistic in prey choices, Accipiters are known hunt strategically. Accipiters show limited association with prey "hotspots" (e.g., bird feeders, nesting areas that contain high volumes of predictable prey) and instead follow time and space unpredictability which gives prey little warning on if/when they could be attacked (Roth and Lima 2007a). While unpredictability in their hunting movement seems random, hawks possess a well-developed sense of direction and location within their home ranges. Movements may be strategically unpredictable, whereby individuals distribute hunting activity evenly over the landscape to reduce likelihood of predator avoidance behavior in their prey.

Hawks also have specific temporal patterns in hunting based on their prey's activity patterns.

Hunting during midday heat is energetically expensive and can deter the movements of prey species as well as the Accipiter species that hunt them. Roth and Lima (2007b), recorded a lack of early morning hunting by sharp-shinned hawks that could also indicate an avoidance of owls – a common predator of this Accipiter species. Cooper’s hawks were also shown to avoid hunting activity in early morning hours.

## Conclusion

Accipiters, or “true” hawks, are unique in their behaviors and genera-specific characteristics. Their nests are found in a variety of ecosystems and their size and construction depends on multiple factors in their environment. Accipiters have a specific sexual dimorphism and unique color morphs. Pair bonds can either be ephemeral or perennial depending on their environmental circumstances, and mating rituals can even include a male building a nest to “impress” a female. Food delivery during brood maturation is performed by the male, young linger near their nests even after fledging, and a newly documented “proning” behavior has recently been documented in some species. These hawks also have very distinct temporal predation and migration patterns and behaviors. Overall, Accipiters are complex birds of prey with complex behaviors and qualities that separate them from other genera in the Family Accipitridae.

## Accipitridae

### ► Accipiters

## Accipitriformes Sensory Systems

Almut Kelber

Lund Vision Group, Department of Biology, Lund University, Lund, Sweden

### Synonyms

Hearing; Magnetoreception; Mechanosensation; Olfaction; Taste; Vision

### Definition

The order Accipitriformes include the families Pandionidae (the ospreys, *Pandion haliaetus* and *P. cristatus*), Sagittariidae (the secretary bird, *Sagittarius serpentarius*), and about 250 species in the family Accipitridae, which has been diverging, since about 34 million years ago, into hawks, eagles, kites, harriers, buzzards as well as Old World vultures (Mindell et al., 2018). The order had earlier been included in Falconiformes but is now recognized as separate order of raptorial birds more closely related to owls (Strigiformes) and New World vultures (Cathartiformes) than to falcons and caracaras (Falconiformes). Accipitriformes are carnivorous birds with sharply hooked bills and curved talons that occur on all continents except Antarctica, with the largest diversity in Africa. They range in size from the pearl kite (*Gampsonyx swainsonii*) and the little sparrowhawk (*Tachyspiza minullus*) weighing 100 g or less to the cinereous griffon (*Aegypion monachus*) and the Himalayan griffon (*Gyps himalayensis*) weighing more than 10 kg.

Sensory systems allow animals to extract relevant information from the environment, adapted to animals' lifestyle and habitat; in birds, the

ability to fly and the feeding habits are most important for the evolution of sensory systems such as vision, olfaction, gustation, hearing, as well as the magnetic sense and somatosensory system (Martin, 2017). These senses allow the birds to navigate and perceive information about conspecifics, predators, food sources, and retreats.

### Introduction

Accipitriform raptors are apex predators and with the exception of vultures and the unusual fruit-feeding palm-nut vulture (*Gypohierax barbatus*), these hunt for prey. While many of them are opportunistic, most have a preferred type of prey, often small mammals or birds, and some are more specialized. The snail kite (*Rostrhamus sociabilis*), for instance, predominately feeds on snails, the bat hawk (*Macheiramphus alcinus*) on bats (Black et al., 1979), and honey buzzards (of the genus *Pernis*) on social insects and honey. Ospreys are cosmopolitan fish-eating birds, and the secretary bird is mostly terrestrial, hunting its prey – including insects, small mammals, birds, lizards, crabs, and snakes – on foot.

A considerable number of accipitriform raptors are long-distance migrators, moving between their breeding grounds in the northern hemisphere and more southerly wintering areas (Nagy et al., 2017). Most accipitriforms are active during daylight but some species can fly during twilight, and few even at night. Some vultures can be observed feeding at night on carrion, but they most likely have arrived at the carcass before dusk. Red-tailed hawks (*Buteo jamaicensis*), African goshawks (*Accipiter tachiro*), and Wahlberg's eagles (*Aquila wahlbergi*) can hunt bats at dusk but not after sunset (see Mitkus et al., 2018), while the bat hawk hunts bats both at dusk and in moonlit nights (Black et al., 1979). The second nocturnal species is the letter-winged kite (*Elanus scriptus*), which hunts bats and nocturnal desert rodents at night (see Mitkus et al., 2018). Raptors that can use powered flapping flight to migrate at night, especially when crossing the sea, include the osprey (*Pandion haliaetus*), honey buzzards, and

the northern harrier (*Circus cyaneus*, see Mitkus et al., 2018).

Little is known about intraspecific communication. Accipitriform raptors are usually brown, with some black, grey, and white. UV reflection from the cere is common, as are yellow to red legs and bills. Most obvious in color is the Egyptian vulture with bright yellow face, and species flushing facial skin color such as the secretary bird, African harrier-hawk (*Polyboroides typus*), and some Old World vultures. Raptors are not usually sexually dichromatic in their plumage, except in a few species including the harriers (*Circus* spp.), and the sparrowhawks (*Accipiter* spp.). The use of adventitious coloration, derived from bathing in mud pools rich in iron oxides, occurs in two species, the bearded vulture (*Gypaetus barbatus*) and the Egyptian vulture (*Neophron percnopterus*; Sarasola et al., 2018).

Courtship flights with male feeding, occasionally in air, require acute vision, while courtship vocalizations (Jurisevic, 1998; Penteriani, 2001) and acoustic communication between parents and their brood rely on good hearing.

## Vision

Accipitriform raptors are famous for their outstanding eyesight but differences are large, both depending on size and between actively hunting species and scavengers such as the vultures. The largest species have two to three times the spatial resolution of humans and thus can see details at two to three times the distance as ourselves. The wedge-tailed eagle (*Aquila audax*), for instance, can resolve gratings of 140 cycles/degree visual angle, and the Indian vulture (*Gyps indicus*) of up to 135 cycles/degree, while the resolution of smaller species is similar or even lower than that of humans (Harris's hawk, *Parabuteo unicinctus* up to 60 cycles/degree; black kite, *Milvus migrans* up to 32 cycles/degree; for references see Potier et al., 2020b). This high spatial resolution is reached only under good viewing conditions in bright light and decreases dramatically in dim light. Even under optimal light conditions, Accipitriformes require relatively high-intensity

contrasts of 10% or more to be able and resolve patterns (see Potier et al., 2020b).

Scavengers tend to have relatively smaller eyes (Potier, 2020) and have only one central fovea – a tiny pit in the retina, in which retinal neurons are displaced while photoreceptors are packed densely allowing for the reported high spatial acuity. In contrast to the human fovea, the central fovea of raptors does not look forward, but sideways. Actively hunting species have a second fovea located in the temporal region of the retina, thus looking forward into the binocular visual field (Potier et al., 2017). This second fovea is probably used to control the talons during prey capture and handling.

Differences between scavengers and hunters are also found in the visual fields. Actively hunting species, such as the short-toed snake eagle (*Circaetus gallicus*), have large monocular visual fields (139 degrees) and wide cyclopean visual fields (259 degrees) with narrow binocular visual fields (20 degrees wide) and large blind sectors behind and above the head (Martin & Katzir, 2000). Scavenging species like vultures, by contrast, tend to have larger binocular visual fields and narrower blind sectors above the head (Potier, 2020).

Like the majority of birds, most Accipitriformes have tetrachromatic color vision, based on four spectral types of single-cone photoreceptors. In Accipitriformes, these are sensitive to violet, blue, green, and red light. Sensitivity to ultraviolet light is low in most species because the ocular lens absorbs most light of wavelengths below 380 nm. Of nine investigated species, the lens of the red kite (*Milvus milvus*) transmits least and that of the marsh harrier (*Circus aeruginosus*) most ultraviolet (Lind et al., 2014; Potier et al., 2020b). In the scavenging cinereous vulture (*Aegypius monachus*) and the nocturnally/crepuscularly active black-winged kite (*Elanus caeruleus*), sensitivity to ultraviolet light is further reduced because the violet-sensitive visual pigment has been lost (Wu et al., 2016), leaving the birds with trichromatic color vision. In addition to the single cones, raptors, like all birds, also have double cones in the retina – two closely intertwined cones with a broader spectral

sensitivity to light of long wavelengths. The function of these double cones is not yet understood, but they are assumed to contribute to the perception of self-motion from optic flow – the movement of the visual image during flight. In Accipitriformes, like in other diurnal birds, rod photoreceptors adapted to see well in dim light are accounting for only about 20–25% of all photoreceptors. Rods and double cones are absent from the central fovea, an additional adaptation to high-resolution color vision (Mitkus et al., 2017; Potier et al., 2018).

Visual information is carried to the brain via the axons of the retinal ganglion cells. Birds have a complete optic nerve crossing and three parallel pathways, the tectofugal pathway to the optic tectum, the thalamofugal pathway to the thalamic nuclei and further the visual Wulst, and the accessory optic system that is thought to contribute to visual flight control.

Accipitriform raptors have slightly faster vision than humans, but only in very bright light conditions, where the Harris's hawk can resolve light flickering with a temporal frequency of up to 78 Hz, which is slower than falconiforms and some passerines (Potier et al., 2020a).

## Hearing

Raptors can use acoustic information for communication (e.g., northern goshawk *Accipiter gentilis*, Penteriani, 2001; black-shouldered kite *Elanus notatus*, and letter-winged kite *Elanus scriptus*, Jurisevic, 1998), to detect concealed prey (*E. scriptus*, *E. notatus*, Jurisevic & Sanderson, 1998), and, in some species, potentially also predators (Sergio & Hiraldo, 2008).

The outer ear of birds is a tube positioned just behind and below the eye, usually covered by feathers but openly visible in vultures (Martin, 2017). Unlike most raptors, harriers (of the genus *Circus*) have an owl-like facial mask improving their directional hearing abilities. The middle ear of birds consists of only two elements, the bony columella and the cartilaginous extracolumella. In the inner ear, the basilar membrane with the sensory hair cells is positioned in the

lagena, a short, slightly curved bony tube. Sound frequency and location of a sound source are coded in the avian auditory midbrain nucleus (Calford et al., 1985).

Hen harriers (*Circus cyaneus*) can locate prey acoustically almost as well as owls from a distance of 3–4 m, and with a resolution of 2 degrees in the horizontal and the vertical plane. This is more accurate than red-tailed hawks (*Buteo jamaicensis*), which have thresholds of 8–12 degrees in the horizontal plane, and much higher in the vertical plane (Rice, 1982). The absolute sensitivity of hearing has been investigated in red-tailed hawks, Eurasian sparrowhawks (*Accipiter nisus*), brown goshawks (*Accipiter fasciatus*), and bald eagles (*Haliaeetus leucocephalus*). All of these have their highest sensitivity to sounds around 2000 Hz, and a broad sensitivity band ranging over 4 octaves. The cutoff at high frequencies was determined as 5700 Hz for the eagles and 8000 Hz for the red-tailed hawks, and low-frequency cutoff lower than 200 Hz. Thus, hearing is similarly sensitive in accipitriform raptors as in songbirds and parrots, but less sensitive than in owls (McGee et al., 2019).

## Chemical Senses: Taste and Olfaction

The birds' sense of smell has long been considered poor, and only recently been investigated in more detail. While birds lack the vomeronasal organ known from many other vertebrates, the olfactory system of many species is well developed, and the number of functional olfactory receptor genes generally quite high (Steiger et al., 2008).

The use of olfaction for finding dead carcasses has been established for New World vultures (Cathartiformes), but little is known about olfaction in Accipitriformes (for a review see Potier, 2019).

Air inhaled through the nostrils passes through three chambers or conchae (Roper, 1999), the first two of which filter out small particles and warm the air, while the third is lined with olfactory epithelium. Similar to falconiform raptors, the golden eagle (*Aquila chrysaetus*) has relatively few olfactory receptor genes but estimations

suggest close to 300 in the oriental honey buzzard (*Pernis orientalis*; Yang et al., 2015). Accordingly, the honey buzzard can detect pollen, important in the species' diet, by olfaction. Anecdotal observations indicate that several species of Old World vultures (of the genera *Gyps* and *Sarcogyps*) may be able to find buried carcasses, likely by olfaction (see Potier, 2019).

It is well known that many birds use preen oil secreted by the uropygial gland for chemical communication, the chemical composition of these secretions have been analyzed only in one species of Accipitriformes, the black kite *Milvus migrans* (Potier et al., 2018). In this species, composition varies between individuals and seasons and during the breeding season, reflects genetic relatedness.

The sense of taste – allowing for the detection and discrimination of chemical and nutrients in food – is even less studied in accipitriform birds. The taste buds of birds are distributed in the oral cavity and tend to be more frequent on the palate, the pharyngeal floor, and the lower mandible than on the tongue. They are often not associated with papillae and connected with the surface by a taste canal (Rowland et al., 2015). Whereas birds have lost of the G-protein-coupled taste receptor that mediates the perception of sweet (Baldwin et al., 2014), they have two genes for bitter receptors (Wang & Zhao, 2015). Sour and salt reception is based on channels rather than G-protein-coupled receptors, and present in Accipitriformes, as in other birds.

## Somatic and Magnetic Senses

Other sensory modalities found in other birds, such as the somatosensory system and a magnetic sense, have barely been studied in Accipitriformes (Martin, 2017). The somatosensory system is based on receptors distributed over the body that allow the birds to detect thermal, noxious, and mechanic stimuli such as vibration, pressure, or air flow (Gottschaldt, 1985). The two types of somatosensory receptors found in the dermis are Herbst (lamellar) corpuscles that are sensitive to vibration and Grandry corpuscles that are sensitive to fast movements (Gottschaldt, 1985). None

of these have been studied in Accipitriformes specifically, even though they must play important roles for behavioral control of flight, feeding, and other tasks.

A magnetic sense has been proven for birds such as passerines and pigeons, in which it contributes to the ability to navigate on large foraging trips and during migration, but the anatomical and physiological basis of this sensory modality has not yet been discovered (Wiltshko & Wiltshko, 2019). While many species of Accipitriformes are also long-distance migrants (Nagy et al., 2017), it has not been investigated whether they also have the ability to sense the magnetic field of the earth.

## Conclusions

Accipitriformes include fast-flying predators, many of which also migrate between over long distances, opportunists and scavengers, which can cover long distances when searching for carcasses. While hunting for prey is largely based on vision, hearing and olfaction may play larger roles than presently acknowledged for raptors. Vision has been studied to some degree, but the other senses are barely understood, and how these fascinating birds navigate during long-distance migration between breeding and wintering areas is largely unknown.

## Synonyms

Acclimation; Acclimatization; Adaptation; Conditioning; Habituation

## Definition

Acclimatization is the process of physiological adaptation by animals or plants due to changes in climatic or environmental conditions.

The process of adjustment of cells or organisms in new environmental conditions including temperature, humidity, photoperiod, and other climatic conditions is called Acclimatization. In order to sustain themselves, during this process, organisms tend to adjust their morphological and biochemical properties in response to new environmental conditions. Depending on the natural characteristics and types of adaptation, the time taken for Acclimatization shows a lot of variation in different organisms ranging from hours to months in some to over a lifetime in others.

Acclimatization is a well-coordinated phenotypic response against environmental stresses that gradually diminishes or lessens relatively upon removal of stressors. Acclimatization occurs in two different phases; i.e., acute stress response and chronic stress response. The acute phase Acclimatization response is under homeostatic regulation and is also known as short-term response. On the contrary, chronic phase response is under homeorhetic regulation and also known as long-term response. When chronic stress persists over several generations, response due to Acclimatization becomes genetically stable and the animal is adapted to the new environmental conditions (Collier et al. 2018). Acclimatization in humans depends on various environmental conditions such as exposure to heat and other climatic conditions. Survival of humans requires significant and increased reliance on these mechanisms (Hanna and Tait 2015).

Climate change is a fundamental challenge for organisms as it deeply and pervasively affects the way they live in their habitats. Climate change not only affects reproduction but also plays a significant role in limiting adaptation activities. Biochemical and physiological changes happening during adaptation are regulated by the change in temperature and gene expression. During Acclimatization in the cold environment, cellular and metabolic changes are observed, which include increased formation of excessive amount of sugars, soluble proteins, organic acids, new protein variants, and change in lipid composition of membranes (Hughes and Dunn 1990). The increase in temperature beyond the average for a number of days changes the adaptation capabilities. Heat waves strongly affect human activities as well as the health and productivity of animals (Pasqui and Di Giuseppe 2019).

Transportation and induction of animals from their adopted conditions to new and unfamiliar conditions are stressful events that result in adverse effects in the general health of animals. The adaptation against these stressful conditions causes several biochemical changes in the animals that allow animals to stabilize in new

environmental conditions in terms of physiological and nutritional changes.

Plants are constantly exposed to biotic and abiotic stresses that reduce their productivity. Plant responses to these stresses are complex in nature and involve physiological and cellular adaptations. It is pertinent to mention that biotic and abiotic stresses also play a significant and positive effect on plant performance in terms of growth, cellular metabolic activity, and adaptability by reducing the susceptibility to stress to a limited extent (Rejeb et al. 2014). Interaction between low temperature and other environmental conditions, e.g., photoperiod and availability of water play a significant role in the Acclimatization of organisms (Pan et al. 1994). Low temperature exposure may alter the growth, habit, and germination of the plants. Acclimatization of plants due to freezing stress is a complex process and the inheritance of frost tolerance is mutagenic in nature (Hughes and Dunn 1996).

## Definition

Gradual development of an association between events that are encountered together.

## Introduction

Events that have biological relevance to the organism can elicit reflexive responses (e.g., food can elicit salivation). Through a similar

process, organisms may produce responses in order to bring forth or prevent the occurrence of a consequence (e.g., following a command to obtain a food reward). In either situation, a link or association between the two events develops, and responses consistent with this association are observed. These responses have the important function of preparing the organism for an impending biologically relevant event or better suiting the organism to maximize reward and minimize punishment in its environment. The process by which paired events become associated is known as *acquisition*.

### What Relationships Are Acquired?

Learning about environmental events can be broadly classified as occurring through classical conditioning or instrumental conditioning. In *classical conditioning*, an environmental event (e.g., a tone) consistently signals the occurrence of a (usually) biologically significant event that naturally produces a response. Consequently, the environmental event also comes to elicit a response (Pavlov 1927). For example, food is an unconditioned stimulus (US) that produces an unconditioned response (salivation). Through repeated pairings, an association between the tone and food is *acquired*, and the tone begins to elicit a salivation response conditional on having been paired with the US. Thus, the tone becomes a conditioned stimulus (CS) that produces a conditioned response (CR) of salivation. Instrumental conditioning is a related process but, in this situation, the association that is *acquired* is between a response (R) produced by the subject and the consequence of that response (reinforcement or punishment;  $S^R$ ; cf. Skinner 1938). For example, a child who cries (R) at the grocery store and receives a lollipop to comfort her ( $S^R$ ) may *acquire* an association between crying and obtaining candy, which will reinforce (increase the likelihood of observing in the future) the response of crying.

### Parameters That Affect Acquisition of an Association

**Contiguity.** Associations are more easily acquired among events that occur in close proximity than among events that are distant from each other. Events that occur close in time to each other are *temporally contiguous*, and events that occur close in space to each other are *spatially contiguous*. For example, touching a doorknob and immediately receiving a static electricity shock would make someone fear touching doorknobs much more likely than if she received the shock a minute afterward. Similarly, if a dog sits and receives a treat immediately upon completing the behavior the likelihood of associating the behavior of sitting and receiving the treat would be much higher than if she received the treat long after sitting on command. When events are not contiguous, it is possible that other events take place between the stimulus and the outcome (e.g., the doorknob-static electricity shock; classical conditioning) or between the response and the outcome (sitting response-treat; instrumental conditioning), and those “other” events may become associated to the outcome. However, it is possible to “mark” the event that is paired with the outcome to “bridge” the gap between the two. Thus, a dog may be presented with a clicker when producing a response, and the clicker again used when the outcome is delivered; the presence of the clicker can act as a bridge between the two events favoring the acquisition of a hierarchical association between the two (see *acquisition of higher-order and hierarchical associations* below). Figure 1 presents different contiguity arrangements between a stimulus and an outcome, as well as an example of a marking procedure.

**Contingency.** *Contingency* refers to the likelihood that two events will occur together as opposed to apart (Rescorla 1968). Some stimulus-outcome or response-outcome pairs are encountered together more often than apart, that is, they have a *positive contingency*. For example, it is very likely that a fall will result in pain, that is, falling and experiencing pain have a strong positive contingency. In contrast, it is very unlikely

**Acquisition, Fig. 1** Common stimulus arrangements with various degrees of contiguity. *Arrows* represent the time line. *Light gray rectangles* above the time line represent CSs, *small black squares* under the timeline represent USs. In delay conditioning, the CS terminates immediately before or slightly overlaps with US delivery. A similar arrangement takes place in long delay conditioning, except that the CS is of long duration. In the trace conditioning situation, there is a gap between CS termination and US

onset during which a memory “trace” is expected to link the two events. In simultaneous and backward conditioning, the CS overlaps with the US or follows US termination, respectively; thus, no *anticipatory* response is observed. The marking procedure is a way to bridge the gap between two events; in this case, the response (R) is “marked” by an event that is repeated immediately prior to delivering the outcome ( $S^R$ ). The mark serves to bridge the gap between the two events

that a fall will result in receiving a static electricity shock; thus, falling and experiencing a shock have a very weak (or near zero) positive contingency. Not surprisingly, we are more likely to acquire an association between falls and pain than between falls and shocks. Responses and outcomes also share some level of contingency. For example, if a child is ignored (outcome) every time she throws a temper tantrum (response), the strong positive contingency between the two events will make it more likely that an association between them is acquired than if they shared a weak positive contingency (e.g., if the child was only occasionally ignored when throwing a tantrum). It is also

possible that events occur more often apart than together. For example, it is very unlikely that a fall will result in muscles becoming relaxed. Thus, there is a strong *negative contingency* between falling and experiencing relaxation. In this case, an association is also acquired, but between the occurrence of a stimulus (or response) and the omission of the outcome. Although there may be some controversy as to whether associations can be acquired to omitted events, some theorists assume that unfulfilled expectations can act as outcomes (e.g., Rescorla and Wagner 1972).

**Stimulus duration.** In general, long antecedents (stimuli or responses) and/or long outcomes

reduce the strength of the response that their association produces. This is not to say that long events do not result in the acquisition of associations, but it is possible that only the portions of those long events that are temporally contiguous to each other become associated. For example, in *inhibition of delay* (or *long-delay conditioning*; Fig. 1) a long stimulus predicts an outcome in its final stages. Usually, subjects come to respond to the final segment of the stimulus, suggesting that they acquire information about stimulus duration and outcome timing. This suggests that “stimuli” and “responses” can be viewed as a sequence of events rather than a single, discrete event (see *Discrete vs. real-time acquisition* below).

**Number of pairings.** The more two events occur together, the stronger the associations that develop among them. As a general rule, the first few pairings result in the greatest behavioral change consistent with acquisition of the association; as pairings continue, the association is presumed to increase in strength but behavioral change becomes less pronounced (see Fig. 2).

**Acquisition, Fig. 2** Schematic response acquisition curve. As the number of pairings between events increases, the response observed as a result of the learning situation is also observed to increase. The curve is said to be *negatively accelerated* because more behavior change (a steeper slope) is observed in the early than the late pairings. Curves *a* and *b* represent differences between two acquisition situations in which the paired events differed in salience, with a steeper slope and a higher level of responding observed to the more salient pair (*a*) than the less salient pair (*b*).

**Stimulus salience and relevance.** In general, stimuli that are more salient or intense acquire associations to their outcomes faster than stimuli that are less salient or intense. In turn, more salient outcomes result in stronger responses than less salient outcomes (see Fig. 2). Operant responses cannot be assessed in terms of salience, but the extent to which they “belong” with the outcome can determine the strength of the association developed between response and outcome (e.g., Breland and Breland 1961). For example, a pigeon will be much faster to learn to peck to obtain food (the response of pecking has high “belongingness” with the outcome of food) than it is to coo in order to obtain food (the cooing response has low “belongingness” with the outcome of food).

## Acquisition of Higher-Order and Hierarchical Associations

Associations can be acquired even in the absence of an outcome of high biological relevance. These associations are often known as *higher order associations*, and they can be viewed as instances in which links among multiple associations are acquired, such that behavior is controlled by a chain of associations rather than a single association. For example, Stimulus 1 may be paired with an outcome and an association acquired among them. If Stimulus 2 acquires associations to Stimulus 1, Stimulus 2 may develop a higher-order association to the outcome and acquire the same capacity to control behavior as Stimulus 1. Fears and phobias are common instances in which higher-order associations develop. An individual who encountered a dog (Stimulus 1) and received a bite (outcome) may come to fear dogs. This individual may also come to fear a park near her house (Stimulus 2) because dogs frequent that park, even if she has never had a negative experience in the park. Money is a general form of a higher order association, in which a reinforcer (e.g., food items;  $S^R1$ ) acquires an association to paper money ( $S^R2$ ), which in turn becomes associated with other forms of currency (e.g., credit cards;  $S^R3$ ).  $S^R1$ ,  $S^R2$ , and  $S^R3$  are known as

**Acquisition, Fig. 3** Schematic representation of higher-order acquisition. *Panel A* presents a higher-order conditioning situation. The *top* represents pairings between a CS (Stimulus 1) and the US (black square under the timeline). The *bottom* represents the higher-order situation, in which a second stimulus (Stimulus 2) is paired with Stimulus 1. As a result of the Stimulus 1-US pairings, Stimulus 1 should elicit a CR; as a result of the Stimulus

2-Stimulus 1 pairings, Stimulus 2 is also likely to elicit a CR when presented by itself. *Panel B* presents a conditioned reinforcement situation. If a Stimulus (Stimulus 2) is paired with a reinforce ( $S^R1$ ), Stimulus 2 may come to acquire reinforcing properties of its own and become a conditioned reinforcer ( $S^R2$ ). Other stimuli that acquire associations to  $S^R2$  (e.g., Stimulus 3) may also become conditioned reinforcers

*conditioned reinforcers*, and they acquire hedonic properties that make them act as effective reinforcers (see Fig. 3 for a schematic representation).

## Acquisition Versus Performance

It may be apparent from the previous section that *acquisition* of an association is not equivalent to *behavioral performance* based on that association. The examples described above presented a direct association between acquisition and performance: A tone paired with food came to produce a salivation response or a dog performed a sitting response to obtain a treat. However, there are also many situations in which there appears to be little relationship between acquisition and performance. For example, an individual on his way to work may often encounter a woman walking her dog. There may be no overt behavior to either woman or dog, but an association may be acquired between the woman and her dog. This association may become evident if, later on, the man develops a phobia of dogs and has a strong emotional reaction when encountering the woman by herself (this is known as *sensory preconditioning* because subjects can acquire associations between sensory events *prior* to conditioning; Brogden 1939). Thus, despite the fact that there was no overt behavior to demonstrate it, there was an

association acquired between two sensory stimuli that were experienced together (the woman and dog). Furthermore, there are also situations in which there appears to be an inverse relationship between acquisition and performance. Situations characterized by a negative contingency between the stimulus or response and outcome may *prevent* a response (this is known as *conditioned inhibition*; Savastano et al. 1999). Thus, even if acquisition has taken place, behavioral performance based on that acquisition may not reflect the nature or strength of the association that was acquired (Miller and Escobar 2001).

## Discrete Versus Real-Time Acquisition

At the theoretical level, there are many different views of acquisition. Some theories suggest that acquisition can be modeled as associations that acquire set amounts of strength in each trial. For example, Rescorla and Wagner (1972) suggested that acquisition is a function of the extent to which the outcome is still surprising (i.e., “how much” of the outcome is not yet predicted by the stimulus). Changes in predictability of the outcome (or *associative strength*) are presumed to reflect acquisition of the association. This approach is simple and predicts many phenomena, but it assumes that acquisition and performance have a

direct relationship, which does not allow the model to explain situations in which an association may exist but it may not be observed in behavior (e.g., sensory preconditioning). Furthermore, a discrete-trials approach ignores the fact that time is a continuum and acquisition could be taking place each instant an event is experienced. Indeed, *real-time* approaches assume that all events can be divided into microelements, each of which can acquire different associations to other microelements within and across events (e.g., Wagner and Brandon 2001). Although these approaches are clearly more realistic, they are also extremely complex and have their own difficulties, such as which time units should be used to determine the duration of the microelements.

### How Does Acquisition Take Place in the Brain?

Acquisition is the basic process that underlies learning and memory. When two events (e.g., a cue and outcome) are paired, their neural signature is activated together and this activity leads to the formation of new synapses and/or strengthening of existing synapses. Classic studies conducted by Eric Kandel in the 1960s with the sea slug *Aplysia californica* confirmed that experience not only results in changes in behavior but also results in cellular changes that can be correlated to the acquisition of new behavior. Experience with paired events can also potentiate synaptic transmission, making it more effective. Thus, subsequent experience of the events can activate the synapses more effectively (a process known as *long-term potentiation*; e.g., Rogan et al. 1997). This increased synaptic effectiveness parallels acquisition of the response, suggesting that the two processes (response acquisition and synaptic strengthening) are closely related.

### Conclusion

Acquisition is a fundamental process that allows organisms to incorporate information about the

environment and use it at a later time to adapt their behavior to the current situation. Many properties of the events that enter into associations determine the rate and extent of acquisition of the association. Associations will be stronger among events that occur in high temporal and spatial proximity (high contiguity), reliably occur together (high contingency), occur together many times (high number of pairings), and which naturally “belong” together (high relevance). Events that are absent can also enter into associations if one of their associates is present in a learning situation, creating higher-order associative links. How acquired associations translate into actual behavior is still a matter of debate because what was learned (acquisition) may not map directly onto behavior (performance). Modeling acquisition is a complicated endeavor because, although acquisition is often represented as resulting in discrete changes in behavior, organisms perceive and use information in real time. Acquisition results in changes in effectiveness of the synapses involved in detecting the relationship between events, suggesting that acquisition is a psychological process with clear physiological implications.

33,500 extant species. The most ancient fossils known of the group are scales from the Late Silurian. The fossil record of the group is more diverse, and the fossils are more complete in deposits of the Devonian and Carboniferous (Choo 2015; Nelson et al. 2016).

Along this 400 million years, the ray-finned fishes evolved reaching almost every aquatic environment in both salt and freshwater, from deep abyssal areas to the highest river basins. Throughout the evolution of these fishes, almost every kind of aquatic habitat has been reached, so that they are found in areas with large differences in temperature, elevation, pressure, salinity, pH, turbidity, luminosity, and availability of oxygen. This diversity of environments reflects the adaptations of the sensory organs and behavior found in the ray-finned fishes species (Helfman et al. 2009). In this entry, we will see more about the structures and senses of the Actinopterygians and how they are adapted to the habitats occupied by these species.

## Actinopterygii (Bony Fish)

Pedro F. Amorim  
Institute of Biology, Federal University of Rio de Janeiro (UFRJ), Rio de Janeiro, Brazil

### Synonyms

Ray-finned fishes

### Introduction

Actinopterygii is the most diverse group of Chordata, with about 470 families and more than

## Anatomy

### Skeleton

The anterior portion of the skeleton on every Actinopterygii is the cranium, where the brain and most sensorial organs are found. This complex structure is divided in **Neurocranium** and **Branchiocranium**. The neurocranium is divided in two portions, each one derived from a different embryonic tissue, **Chondrocranium** and **Dermatocranium**. The chondrocranium is formed from endochondral bones, meaning that the brain case is originally cartilaginous, which is later replaced by bones during the ontogenetic development. The dermatocranium develops from dermal bones, which are derived from groups of scales that change into bones. The histology of both kinds of bones is very similar; however, the embryonic development is completely different. The neurocranium is usually divided in four areas, each one associated with a different sense organ: (1) ethmoid region (related to the olfactory nasal capsule); (2) orbital region (around the eyes); (3) optic region (encompassing

the ear chamber); and (4) basicranial region (connecting the brain to the spinal cord).

The branchiocranium, also known as visceral cranium, is composed of the bones present in jaws, branchial, opercular, pharyngeal, and ventral orbital regions of the cranium. This portion is derived from dermal bones. It is in the branchiocranium where the teeth are usually found among the species of Actinopterygii. The teeth are found not only in the jaws, but they also may occur in branchial and pharyngeal bones. There is a great diversity of teeth forms among ray-finned fishes: (1) caniniform (tooth is slender and conical); (2) cardiform (thin teeth ordered in a series of rows); (3) molariform (robust teeth used to smash food); and (4) villiform (short and pointed teeth). Other patterns found in Actinopterygii include: (1) teeth fused in a plate; (2) triangular arrowhead shaped teeth; and (3) species with no teeth in the jaws but only in pharyngeal bones.

In the vertebral column, each vertebra develops from cartilaginous structures named arcualia. The formation of vertebrae may occur in two different ways: (1) monospondylus, when there is only a single vertebra for each arcualia, and (2) diplospondylous, when two vertebrae are formed from each arcualia. Among Actinopterygii, the diplospondylous condition is only found in the monotypic order Amiiformes. Two kinds of vertebrae are recognized in each species of Actinopterygii: (1) precaudal vertebrae, present from the anterior portion of the column to the end of the body cavity, and (2) caudal vertebrae, in the posterior portion of the body. The caudal vertebrae feature a closed hemal canal and a completed hemal spine ventrally. The dorsal portion of both caudal and precaudal vertebrae is similar, presenting a neural spine supported by the neural arches.

Ribs and intramuscular bones are found next to precaudal vertebrae. Most of Actinopterygii have the pleural ribs distributed between the third and the last precaudal vertebrae, and these structures are positioned around the visceral cavity protecting the organs. Other intramuscular bones found in Actinopterygii are epineurals, epicentrals, and epipleurals.

The final portion of the Actinopterygians body is the caudal fin, which is a complex structure composed of vertebral centrum, vertebral accessories, and also fin rays. Over the different Actinopterygii lineages, the caudal fin has been modified, adapting to each environment reached by the ray-finned fishes. The classification of caudal fins is based on dorsal-ventral symmetry and the internal morphology of the fin. In Actinopterygii, there are two kinds of fins found: heterocercal and homocercal. Species with heterocercal pattern present the column extending to the superior portion of the tail, in the dorsal lobe. This type of fin is observed in the plesiomorphic orders Acipenseriformes (sturgeons and paddlefishes), Lepisosteiformes (gars) and Polypteriformes (bichirs and reedfish). The second pattern found in Actinopterygii is the homocercal, in which the caudal fin is symmetric externally and internally. This internal symmetry is possible due to a series of bones named hypurals, positioned after the last vertebra. The external symmetry comes from the disposition of the caudal-fin rays connecting with the hypurals. Only one species presents the caudal fin externally symmetric but not internally, *Amia calva*, the Bowfin (Amiiformes). This intermediate pattern is named hemihomocercal.

Three kinds of unpaired fins may be found in Actinopterygians: dorsal fin, anal fin, and adipose fin. These fins are always aligned with the sagittal plane of the body, with the dorsal and adipose fins positioned dorsally and anal fin ventrally. The dorsal and anal fins are externally supported by lepidotrichia, small bones derived from scales. Internally these fins are held by radials, which are named interneural bones in the dorsal fin and interhemal bones in the anal fin.

Plesiomorphic lineages of Actinopterygii have only one dorsal fin with soft rays. In Teleostei, an anterior dorsal fin with spines is found; in species with two dorsal fins, the first is always composed of spines and the second by soft rays. The primary function of the dorsal fin was related to making the swim more stable, but this function has been modified along the evolution of different lineages. Some of the most abrupt

changes are found in remoras (Echeneidae), in which the dorsal fin is modified into a suction disk allowing these fishes to attach themselves to larger animals, and in anglerfishes (Lophiiformes), the dorsal fin spine is modified in a structure named illicium and is used as a fishing rod to capture preys.

Unlike the dorsal fin, few lineages show diversification in the anal fin. In some families of the order Cyprinodontiformes, males have the anal fin modified as a reproductive structure, the gonopodium. A similar modification may be found in the genus *Zenarchopterus* (Beloniformes), where the anal fin is modified in an andropodium. In some lineages, as Gymnotiformes and Notopteridae (Osteoglossiformes), the anal fin is used as the main locomotory structure.

The adipose fin is an extra fin found in some lineages of Teleostei, positioned posterior to the dorsal fin. Despite the name, this fin is not usually composed of adipose tissue. Lepidotrichia and bones of support are generally absent in this fin. The adipose fin has evolved independently in different lineages, yet, the function of this fin is still unknown.

Ray-finned fishes present two pairs of paired fins, the pectoral and pelvic fins. The pectoral fin is positioned in the anterior portion of the flank. The pectoral-fin rays are supported by radials attached to the pectoral girdle. In tetrapods this girdle is connected with the vertebral column. However, in Actinopterygii, the pectoral girdle is connected to the posterior portion of the neurocranium. The pelvic fin is positioned in the ventral portion of the body, anterior to the anal fin. Plesiomorphic groups present the pelvic fin in an abdominal position; however, along the evolution of the ray-finned fishes, this fin became anteriorly positioned in the thorax or even assuming a jugular position. Pelvic fins in jugular position may be found even anteriorly to the pectoral fins. The pelvic girdle of tetrapods is connected to the vertebral column. In ray-finned fishes, the pelvic girdle usually has no connection with other structures, except for the species with jugular pelvic fins, that are generally connected with the pectoral girdle.

## Scales

Scales are found covering the body of almost every species of Actinopterygii. In this clade there are two basic kinds of scales: (1) the ganoids and (2) the cycloids and ctenoids (Roberts 1993). Ganoid scales are found in Polypteriformes, Acipenseriformes, and Lepisosteiformes. This scale generally presents spots of connection and articulation. Sturgeons and Paddlefishes (Acipenseriformes) show the most modified ganoid scales, which are featured as large plates letting most of the body naked, covered only by the skin. Cycloids and ctenoids scales are found in Teleostei and have two main layers. The first one is composed of salts (mostly calcium carbonate and hydroxyapatite) distributed in an organic matrix. The second layer is more internal and mainly composed of collagen fibers. These scales are aligned overlapping the next scale, giving much more flexibility to the individual than ganoid scales. Cycloids and ctenoids scales differ from each other due to the absence of ctenii (spinules on posterior margin) in cycloid scales. There are three kinds of ctenoid scales: (1) crenates, with spines only in the margin of the scale; (2) spinoids, when the ctenii reach the main body of the scale; and (3) ctenoids, with the spinules found as ossifications separated from the scale. During the ontogenetic process, the development of the scales begins on the caudal peduncle in the lateral line. After this, the scales advance in dorsal and ventral rows parallel to the lateral line, propagating to the anterior portion of the body. When the progress of the scales is finished, their number remains unchanged during the life of the individual.

## Cardiovascular System

This system is responsible for the distribution of nutrients, excretory metabolites, and respiratory gases, making the cardiovascular system also important for osmoregulation, excretion, and respiration. In Actinopterygii, the basic pattern of the blood flow starts in the heart, proceeds to the gill arches, and one part goes to the head and another part to the body, and then back to the

heart. The pericardial cavity shelters the heart, and this cavity is positioned posteriorly and ventrally to the gill arches. The heart of Actinopterygians is divided into four sequential chambers: sinus venosus, atrium, ventricle, and bulbus arteriosus (Farrell and Jones 1992). The last chamber is a nonmuscular bulbus, which stabilizes the pressure of the blood coming from the ventricle. When compared with tetrapods, the heart of ray-finned fishes shows a very small weight relative to the body weight. Lethargic species present a proportion of less than 0.1% between heart weight and body weight. More active species have heavier hearts, but never reaching more than 0.25% of the body weight.

## Respiratory System

Aquatic breathing demands more energy than aerial breathing. While the oxygen composes about 20% of the atmosphere, in water environments this gas may be diluted in less than 1%. Thus, the respiratory system of the Actinopterygians needs to extract as much oxygen as possible from the water (Graham and Lee 2004). The organs responsible for gas exchange are the gills. They have an osteologic structure supporting the secondary lamellae (thin membranes well-vascularized with a large surface).

Oxygen is absorbed and carbon dioxide is released by diffusion, and to optimize this process the blood in the secondary lamellae flows in countercurrent with the water passing through the gills. This opposite flow is necessary for the correct function of the gills. To ensure this countercurrent flow, two strategies are used by the Actinopterygii species. The process most commonly used is to alternate the size of the oral and opercular chambers, increasing and decreasing the volumes. The water flows from the mouth to operculum keeping the correct direction and the respiratory cycle. The second process is named ram ventilation, where the individuals simply swim with the mouth slightly opened, keeping the water flow through the gills. Ram ventilation is used by pelagic high-speed species and it saves

energy, since only the swim muscles are used to breathe, in opposition to the previous pattern of ventilation.

In some species the oxygen may also be acquired from the atmosphere. Gills usually need to be in an aquatic environment to keep the correct shape, since when exposed to an aerial habitat the gills collapse and stick together, making gas exchange impossible. Therefore, species with this ability to breathe atmospheric air also present morphological adaptations in some structures to enable them to utilize the atmospheric air. Those modifications are divided into three categories: (1) species with air-breathing organs derived from the alimentary tract, as gas bladder, stomach or intestines; (2) modifications in the head, such as gills modified to work properly in atmospheric environments; and (3) a well vascularized skin allowing the cutaneous gas exchange (Graham 1997).

## Swim Bladder

The bladder is filled with oxygen, nitrogen, and carbon dioxide, being also known as gas bladder. The function of this organ has changed through the Actinopterygii evolution, as probably the original function of the gas bladder was similar to the one of a lung. In extant species this bladder is used mainly for hydrostatic and buoyancy control, although in some species the swim bladder is also used for breathing and in sound perception or production. In some deep-sea or benthic species, this bladder is lost. The most internal layer of the swim bladder, the bladder epithelium, has a different origin than the other layers, as this epithelium has an endodermic origin, while the other tissues are derived from the mesoderm.

Two kinds of swim bladder are found in adults of Actinopterygii: physostomous and physoclistous. In physostomous species, the acquisition and release of gas occurs by a connection between the swim bladder and the alimentary tract, called the pneumatic duct. The physostomous pattern is plesiomorphic among the ray-finned fishes, and species

with adults presenting the physoclistous pattern, juveniles present a physostomous swim bladder.

In physoclistous species there is no duct connecting the bladder with other organs, and the addition of gas is performed by the gas gland. This gland transfers gas dissolved on the blood, by diffusion, to the air bladder. The gas is released by a modified area of the swim bladder, called the oval. This structure transfers the air to the blood, and the excess gas is carried to the gills and released in the environment.

## Nervous System

In Actinopterygii, the nervous system is divided into cerebrospinal, encompassing the central nervous system and peripheral nervous system, and the autonomic systems, with sympathetic and parasympathetic ganglia.

The central nervous system contains the brain and spinal cord. Anatomically the brain is divided into five portions: telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon. Each portion has a different function, processing information of different parts of the body. The telencephalon is responsible for the perception of the olfactory system; this part of the brain is homologous to the brain of tetrapods. The diencephalon function is to connect the information arriving and departing related to the endocrine system and homeostasis. In the dorsal portion of the diencephalon there is a well-vascularized structure named pineal body. The function of this structure is associated with color change, seasonal cycles, and circadian clock. Despite being a structure of the brain, the pineal body has light-sensitive cells, similar to the retinal cones. The mesencephalon is connected with the optic nerve, and all the information received by the eyes is processed by this portion of the brain. The next portion of the brain is the metencephalon, which comprises the cerebellum, responsible for the equilibrium of the swim, eye muscles, and muscular tonus. The last portion of the brain is the myelencephalon, controlling osmoregulation, breathing, and transmitting the information of each sensory systems,

with the exception of the olfactory and visual systems. The myelencephalon also connects the brain to the spinal cord.

## Sensory Systems

An important step to understand the sensory systems of Actinopterygians is to be aware that the perception of stimuli in aquatic environments differs from that in aerial environments. Taste and smell, that are very different from each other for land organisms, are very similar in water. Some wavelengths of light begin to fade according to the depth, and the sound travels faster and further than through the air. The perception of the environment may also change along the ontogeny of some species, when adults and juveniles are found in different niches (Poling and Fuiman 1998; Braun et al. 2002).

### Mechanoreception

In Actinopterygii, this sense perceives the vibration of the water. These stimuli are received by sensory hair cells, featuring cilia (Schellart and Wubbels 1997). Modifications on the vibration of the water change the frequency of nerve impulses emitted by the sensory cell to the brain. Two main mechanosensory systems are found in ray-finned fishes: the lateral line (receiving stimuli of turbulence around the fish, helping in hunting, positioning in school, and avoiding obstacles) and the inner ear (helping in hearing and equilibrium).

Among the Actinopterygii the lateral line system is a plesiomorphic feature, found even in Silurian fossil jawless fishes. The sensitive hair cells of this system are found clustering together with a gelatinous dome covering the cells, in a structure named neuromast. The function of the gelatinous cupula is to protect the hair cells from background noise, thus only stronger vibrations will be detected by the neuromasts. In the lateral line system, the neuromasts may be found in two possible conformations: (1) free neuromasts over the skin, or (2) in channels under the skin and scales (in the trunk) or dermal bones (in the head).

In the early ontogenetic stages of ray-finned fishes, all neuromasts are superficial and mostly disposed on the head. Along the development the distribution of the neuromasts extends to the trunk and the channels are formed encompassing them, under the skin. Those channels have pores, allowing the water to enter and interact with the neuromasts. The protection provided by the channels helps to avoid the permanent background noise of the water around the fish, making those neuromasts very sensitive to modifications on the water flow or high frequency vibrations (20–100 Hz). This kind of neuromasts is usually well-developed in species inhabiting turbulent waters habitats or in fast swimmers. Superficial neuromasts are more sensible to movements in environments of slow currents and low frequencies (below 20 Hz), making them very useful to detect preys and predators. Free neuromasts are more abundant in species inhabiting slow current environments and sedentary species.

Hair cells are also responsible for equilibrium and balance of ray-finned fishes. In the pars superior of the inner ear, there are three semicircular canals, that contain endolymph, and the terminal ampulla, connected with the semicircular canals, containing sensory hair cells. This portion of the inner ear receives the stimuli related to equilibrium and balance. The movement of the fish is reflected in the endolymph and changes in the posture, orientation, or speed are perceived by the hair cells. These cells send this information to the brain, which analyzes and corrects the balance and equilibrium of the individual.

The cavities of inner ear named saccule and lagena (in pars inferior) and utricle (in pars superior) are the portions responsible by hearing. Each cavity holds an otolith (structures of the inner ear made from calcium carbonate), which is surrounded by the otolithic membrane. This membrane connects the otolith with the tissue of the cavity. The tissue of each cavity is composed of sensorial hair cells that send to the brain the information from mechanic stimuli related to the sound. Otoliths react to the vibration due to their density. Most structures of the ray-finned fishes body have the same density as water, not interacting with its vibration. However, the

vibration of the water may interact with spaces filled with gas inside the body of the fish, such as the gas bladder. Some species have adaptations that connect the gas bladder to the inner ear, improving their hearing. Better hearing species include cods, in which the anterior portion of the bladder is positioned very closely to the inner ear; sardines, in which the gas bladder is in contact with the inner ear; African mormyrids, which present independent gas bladders close to the inner ears, and the Othophysi species. In the species of Othophysi, small bones connect the gas bladder to the inner ear. This adaptation is derived from the modified anterior vertebrae, and this structure is named Weberian ossicles. Thus, the vibration of the gas bladder is directly transmitted to the inner ear, making the hearing of Othophysi the most complex and accurate among the Actinopterygii.

### Chemoreception

In aerial environments the difference among olfaction, the sense of molecules dissolved in air, and gustation, the perception of chemicals dissolved in water, is very clear. However, for species inhabiting aquatic environments, those limits are not so clear, and chemoreceptors may be found in different structures than just mouth and nostrils. Several kinds of molecules dilute in water and the capacity of noticing these molecules allow the ray-finned fishes to locate shelter, to communicate with other individuals, to find food, and to evade predators. In Actinopterygii, the chemoreceptors related to the perception of the environment are usually associated with the olfaction, whereas the receptors related to the identification of the food are generally linked to the gustation (Hara 1986).

The chemoreceptors of the ray-finned fishes are mainly concentrated in the paired olfactory chambers. These structures are invaginations usually on the anterior portion of the head. Inside the chambers there is the olfactory epithelium usually organized in rosettes. The stimuli received by this tissue are transferred to the olfactory lobes of the brain. Inside the chamber there are cells with cilia generating the movement of the water through the sensitive cells. This water flux allows the

animal to continuously perceive the molecules around. Among the ray-finned fishes the olfaction is mainly used to find partners, receiving stimuli of sex steroids, of pheromones, and of alarm substances. Thus, this sense is extremely important to avoid predators and to reproduction. Damages in those receptors may affect the behavior of the individual, disturbing the social interactions of the specimen.

The sense of taste in Actinopterygians is mainly used to recognize what may be eaten. Sensory cells responsible for the gustation may be found isolated or grouped in taste buds. Isolated cells may be very abundant, with up to 4000 per mm<sup>2</sup>. The taste buds contain a smaller number of cells, usually between 30 and 100. Those chemoreceptors are found inside the mouth but also in structures around the mouth, as lips and barbels, or even in trunk and fins.

### Vision

In aquatic environments the intensity of light and the wavelength available differ according to the depth and to what chemical substances are dissolved in the water, as salts and organic matter. These differences among the habitats lead to distinct adaptations related to ray-finned fishes vision organs. Wavelengths closer to the red end (lower frequencies) are the firsts to disappear with the increasing depth, while those closer to the violet end (higher frequencies) reach deeper into water. Despite that, ultraviolet light does not reach very deep in the water (Guthrie and Muntz 1993).

The morphology of the ray-finned fishes' eyes is very similar to the other vertebrates. The most external layer is a thin transparent cornea, followed by the pupil. Unlike tetrapods, in which the pupil diameter is variable according to the light available, in Actinopterygii the pupil size is fixed. The next structure found in the eye is a spherical lens, contrasting with the eyes of tetrapods, which have a convex and less dense lens. The center of the eye is a cavity filled with liquid, the posterior portion of which is composed of the layers of the retina, where the light stimuli are received by the photosensory cells and sent to the brain. In Actinopterygians, the focus of the image inside the eye is obtained by moving the lens to anterior or posterior portion of the eye,

adjusting according to the distance between the fish and the object (Hawryshyn 1998).

Two kinds of photosensory cells are found in the retina of Actinopterygii species: cones and rods. Rods are the most sensitive to the light, allowing to see even with low light. However, these cells generate images with low resolution. The rods are more numerous in species occupying niches with low light, as deep sea, nocturnal, or crepuscular species. Cones have a lower sensitivity to light, and therefore more light is necessary to stimulate it, but these cells can generate images with higher resolution than rods. These cells are sensitive to different wavelengths, depending on which kind of opsin, the photoreceptive glycoproteins, is present in each cell. Cones with porphyropsins perceive longer wavelengths, or colors between red and yellow. These cells are usually found in species living near the water surface. Photosensory cells with rhodopsin are sensitive to wavelengths of the colors between green and blue; thus, these cells are more common in species living in habitats somewhat deeper. In species inhabiting deep sea areas, the most usual opsin found in the cones is the chrysopsin, and these cells detect colors from blue to violet, which reach deeper in the water. In some species inhabiting areas near the surface or shallow habitats, an opsin sensible to ultraviolet light also may be present.

As the light intensity may vary according to each habitat, the Actinopterygii species feature three types of cones, with a few species featuring more than three or only two types. The arrangement of the photosensory cells may vary according to the habitat of the species and also along the ontogenetic development. In some species in which juveniles and adults occupy different niches, not only the distribution of the cells may be modified, but even the opsin expressed by each cell may be modified. Despite the variety of light wavelengths that can be detected by Actinopterygians, reaching even ultraviolet light, some species are also able to see polarized light.

In most species of ray-finned fishes there is a U-shaped choroid gland around the optic nerve. The function of this gland is to provide oxygen to the retina because of its high need for the gas. The last part of the eye is the sclera, a layer

to protect those delicate internal structures. In Actinopterygii, the sclera is usually found as sclerotic bones, while in Myxiniiformes and Petromyzontiformes the sclera is fibrous, and in Chondrichthyes this structure is presented as cartilaginous plates.

Between the retina and the protective sclera there is a well-vascularized layer named choroid. In a few species of Actinopterygii the choroid may present a tapetum lucidum. This is a structure made by guanine crystals that reflect back to the eye the light that passed through the retina and was not absorbed by it. This adaptation increases the visual perception in conditions of low light.

### Electroreception

In Actinopterygii, few groups have the capacity to feel electric fields. This sense is perceived by electroreceptor organs that only have evolved in some lineages. The cells that compose this organ are derived from mechanoreceptor hair cells during the ontogeny (Whitehead and Collin 2004). In ray-finned fishes, there are two kinds of electroreceptor organs: ampullary receptors and tuberous receptors.

Ampullary receptors are found in invaginations of the skins. Externally there is a pore, connecting the receptors to the environment. This pore leads to a canal containing a conductive gel, and to the receptor. This kind of organ detects stimuli of low frequency electric fields, between less than 0.1 and 25 Hz, perceiving electrical signals coming from other animals. In this organ the perception of electricity is due to differences in electric potential between the apical and basal membranes.

Tuberous receptors are placed over the skin, covered by a layer of epithelial cells. These receptors are sensitive to electric fields of higher frequency, between 50 and 2000 Hz, and are used for electrolocation, detecting electric pulses of the individual itself. Thus, only species with electric organ discharge have tuberous receptors. These receptors may be divided into two main kinds according with which stimuli are detected: the frequency of the pulses or their amplitude. With those receptors the individual is able to detect any kind of object passing through the coverage area of the electric field. Electric organs

are composed of modified muscle cells named electrocytes (Von der Emde 1998). These cells usually have a disk-like shape and are arranged in rows. The electric pulse is generated by an ion flux over the membrane of the electrocytes. Each cell generates a small electric current, but because they are aligned in rows and the electric discharge is simultaneous, the effect is additive, amplifying the discharge, as little batteries in a row.

### Reproduction

Several kinds of reproductive patterns are found among Actinopterygii species, the differences range from the number of mating partners along the life of the individual, to the existence or not of parental care. For most species of the group the sex of the individual is defined in early life stages and kept along the lifetime (Bone and Moore 2008). Nevertheless, in some species both gametes are produced, and this species are divided into two categories: simultaneous hermaphrodites and sequential hermaphrodites. Species considered simultaneous hermaphrodites are very rare, and the individuals are able to produce fertilized eggs, or sperm and eggs in one spawning. Sequential hermaphrodites change the gender along the lifetime, and all the reproductive structures correspondent to the present sex become functional. Species in which individuals are born as females and become males throughout development are named protogynous, and species where the first stage is male and the second female are named protoandrous (Emlen and Oring 1977).

Most of the ray-finned fishes' species have more than one opportunity to reproduce in their lifetime, and these species are named iteroparous. However, in a few species only one single spawning event occurs in life. These species are known as semelparous, and they are usually diadromous or perform a great migration. Diadromous species are divided into two kinds: (1) anadromous (the individuals are born in freshwater, migrate and grow in the sea, and then migrate back to freshwater to reproduce) and (2) catadromous (the individuals are born in the sea, migrating to freshwater to grow, and then migrate to the sea to reproduce). A well-known example of

semelparous species is the salmon, living most part of the life in the sea but going up rivers to spawn.

The number of reproductive partners also varies in the different species of the group, and may be divided into three main patterns. (1) Promiscuous species, when the partner is chosen with little or no degree of selection. In those species multiple individuals of both sexes spawn together at the same time or in a short time. (2) Monogamous species, in which the individuals remain breeding exclusively with the same partner. In this case, the couple not necessarily stays together after the mating season. (3) Polygamous species, in which individuals of only one sex have many partners. When the female presents several partners it is named polyandry, and when the male has different partners it is called polygyny, which is more common. Among the polygynous strategies the formation of harems may also be found. In this case a group of females stay with one male and only reproduces with him, who protects the whole group. Another strategy comprised by the polygamous pattern is the formation of leks, in which many males concentrate in a specific area only to display to females.

Most of the ray-finned fishes' species leaves the eggs after spawning, not presenting any kind of parental care. However, this behavior is found in several lineages of Actinopterygii, in different levels and time periods. The first stage of parental care includes to build a nest. In some species the eggs are buried in the nest after the spawning and the parents leave the eggs. Other species stay with the nest until the birth of the offspring, protecting the eggs from predators, cleaning the nest, removing sediments, unviable eggs, and keeping a water flux to maintain the eggs oxygenized. In other species the eggs are eventually carried in the mouth to provide a better protection to the offspring. In some species the development of the eggs is internal, and this kind of bearing is divided in ovoviviparous (when the eggs are kept inside the mother and embryos feed on the yolk present in the egg) or viviparous (when there is a specialized tissue responsible for feeding the embryos and performing gas

exchange). In a few species, after the birth, the adults also may produce mucus to feed the juveniles or help them to obtain food.

Hofstra University, Hempstead, NY, USA

## Synonyms

Neural impulse

## Definition

An action potential is a brief event that occurs when there is a change in the membrane potential, or electrical activity, of a neuron.

## Introduction

Action potentials play an integral part of communication between neurons and are involved in many processes within the central nervous system, neuromuscular junctions, and cardiac functions. They occur in response to a stimulus, such as sensory input or neurotransmitters, usually through the dendrites of the neuron. These stimuli cause small excitations in the dendrites or cell body called graded potentials. Graded potentials are summated and must be strong enough to trigger the impulse. At rest, the inside of a neuron is negative relative to the outside. Once it is stimulated, the intracellular environment becomes positive relative to the outside of the cell, thus allowing ion channels to open and sodium ( $\text{Na}^+$ ) to move into the axon. Most neurons have a protein called myelin that surrounds segments of the axon and insulates them from extracellular electrical activity. Small sections that remain unmyelinated are referred to as nodes of Ranvier. These nodes contain many ion channels that help the action potential regenerate as it travels down the axon. Myelin allows for the action potential to quickly travel from node to node, as it promotes low resistance for the conduction of positive ions. This action of jumping from node to node is called saltatory conduction. Once the action potential travels down the axon, there is a positive spike in the membrane potential that causes a release of neurotransmitters into the synapse through the neuron's terminal buttons.

## All-or-None Principle

A neuron is connected to thousands of other neurons; therefore it can receive numerous stimuli at one point in time. The strength of the stimuli does not affect the amplitude, or intensity, of an action potential. In addition, an action potential is only generated if there is sufficient stimulation. These properties make up the all-or-none principle. In other words, an action potential will have the same intensity of firing regardless of the intensity of a stimulus. While the strength of the stimulus does not affect the intensity of the action potential,

it does affect the frequency of firing (Barnett and Larkman 2007).

## Measurement of an Action Potential

An action potential can be measured by recording the electrical potential of the cell membrane using electrodes. Electrical activity is most commonly measured using two points, one as a reference and another to record changes in potential, relative to the reference point. The extracellular environment is used as the reference point for recording electrical changes in a neuron. When the recording electrode is inserted into the axon, a negative potential is measured. This indicates that, at rest, the inside of the neuron is more negative than the extracellular environment.

Each ion involved in the action potential has a concentration gradient due to the permeability of the membrane. The potential for each ion can be measured by the Nernst equation:  $E_i = \frac{RT}{zF} \ln \frac{[C]_o}{[C]_i}$ . In this equation  $E_i$  indicates the equilibrium of a single ion,  $R$  is the Universal Gas constant,  $T$  is temperature,  $z$  is the charge of the ion,  $F$  is Faraday's constant,  $C_o$  is the concentration of the ion outside the cell, and  $C_i$  is the concentration of the ion inside the cell (Hille 2001). Outside of the cell, there is a high concentration of sodium, calcium, and other ions, while the inside has a high concentration of potassium ( $K^+$ ). Each of these ions has an equilibrium potential ( $E_i$ ) as a result of the concentration gradient.  $Na^+$  has a positive equilibrium potential ( $E_{Na^+}$ ) of about +55 mV.  $K^+$  has a negative equilibrium potential ( $E_K$ ) of about -75 mV (Barnett and Larkman 2007). The resting potential of the cell is at about -60 mV. As ions move across the membrane, the membrane voltage ( $V_m$ ) and permeability change. In order to calculate the membrane potential of a cell, the Goldman equation is used:  $V_m = 58 \log \frac{P_K[K]_o + P_{Na}[Na]_o + P_{Cl}[Cl]_i}{P_K[K]_i + P_{Na}[Na]_i + P_{Cl}[Cl]_o}$ , where  $P$  indicates the permeability of the cell (Purves et al. 2001a).

During an action potential (Fig. 1), the  $Na^+$  channels open and  $V_m$  increases or depolarizes, toward  $E_{Na^+}$ . As more  $Na^+$  rush into the cell, a

positive feedback loop occurs.  $Na^+$  increases  $V_m$ , which opens more voltage-gated ion channels, allowing more  $Na^+$  into the cell, further increasing  $V_m$  toward  $E_{Na^+}$ . The loop repeats until all the  $Na^+$  channels open and the cell reaches the peak voltage of the action potential, meaning the concentration of  $Na^+$  is equal on both sides of the membrane. This point is known as the absolute refractory period. During this period, no more  $Na^+$  can enter the cell to create another action potential. The high  $V_m$  then inactivates the  $Na^+$  channels and opens the voltage-gated  $K^+$  channels. As this occurs,  $K^+$  rush out of the cell and  $V_m$  decreases or repolarizes, toward  $E_{K^+}$ . During this period, action potentials are unlikely but possible only in response to strong stimuli. This is known as the relative refractory period. Since  $E_K$  is lower than -60 mV,  $V_m$  falls under the resting potential resulting in hyperpolarization (Purves et al. 2001a). The cell then repolarizes back to resting potential via the sodium-potassium pump.

## Sodium-Potassium Pump

A neuron maintains a resting potential around -60 mV due to an electrochemical gradient created by the active transport of the sodium-potassium pump ( $Na^+/K^+$  pump). This transporter works by pumping three  $Na^+$  ions out and two  $K^+$  ions into the cell. At rest, the extracellular environment has a higher concentration of  $Na^+$ , while the intracellular environment has a higher concentration of  $K^+$ . The  $Na^+/K^+$  pump requires ATP as energy because it moves the ions against their concentration gradients. This action results in a deficit of positive ions inside the cell making it negative relative to the extracellular environment (Glitsch 2001).

## Initiation

There are three steps to the occurrence of an action potential: initiation, propagation, and termination. Initiation of the action potential begins with a stimulus that causes ion channels to open, usually on the dendrites or cell body. A stimulus can be excitatory or inhibitory. When a neurotransmitter binds

A

**Action Potentials, Fig. 1** Stages of action potential. Membrane potential starts at rest at  $-70$  mV. Once threshold is reached at  $-45$  mV, the membrane potential depolarizes toward the  $\text{Na}^+$  potential at  $+55$  mV. At this point, known as the absolute refractory period, another action potential cannot occur because no more  $\text{Na}^+$  can enter the

cell. The membrane then repolarizes to the equilibrium potential of potassium at  $-75$  mV. During this stage, the relative refractory period, only strong stimuli can elicit another action potential. The membrane then goes back to resting potential by action of the sodium-potassium pump

to a receptor that increases the probability for depolarization, it is called an excitatory postsynaptic potential (EPSP). When a neurotransmitter binds to a receptor to increase the chance for hyperpolarization, it is called an inhibitory postsynaptic potential (IPSP) (Purves et al. 2001b). EPSPs and IPSPs alter the permeability of the membrane by affecting the ion channels (Krnjevik 1987). Positive or negative ions enter the cell body and work their way along the membrane toward the axon hillock, where they are collected and summated. This movement across the membrane causes small variations in electrical potential of the cell, known as graded potentials. The graded potentials must sufficiently depolarize the cell and bring the membrane potential to a threshold, usually  $-40$  mV, in order for an action potential to occur. Once the membrane potential reaches the threshold, the axon hillock experiences a reversal in charge, where it becomes positive relative to the outside of the cell (Palmer and Stuart 2006).

## Propagation

Once the action potential is initiated, the positive charge in the axon hillock is propagated to the adjacent, unmyelinated segment of the axon (Palmer and Stuart 2006). As the flow of positive ions moves into adjacent segments,  $\text{Na}^+$  and  $\text{K}^+$  voltage-gated ion channels are activated.  $\text{Na}^+$  channels open first, allowing the positive ions to rush into the cell (Fig. 2b). Once the inside of the axon becomes positive, the channels deactivate via a ball and chain mechanism in which a ball blocks the channel, preventing further  $\text{Na}^+$  from entering the cell (Fig. 2c). This systematic deactivation is called the refractory period and prevents the action potential from moving backward. Furthermore, the negative electrostatic charge in the following segment pulls the positive ions forward. As the  $\text{Na}^+$  channels inactivate, voltage-gated  $\text{K}^+$  channels open and allow  $\text{K}^+$  to move out of the cell, following their concentration gradient

Action Potentials, Fig. 2 (continued)

(Fig. 2d). This is known as repolarization. The  $K^+$  channels are slow to deactivate and bring the segment below resting potential, hyperpolarizing it (Fig. 2e) (Barnett and Larkman 2007). The action of the  $Na^+/K^+$  pump brings each segment back to resting potential from the hyperpolarized state.

## Termination

### Chemical

Termination takes place when neurotransmitters are released into the synapse through the neuron's terminal buttons. When an action potential reaches these buttons, the positive charge opens voltage-gated calcium ( $Ca^{++}$ ) channels.  $Ca^{++}$  rush into the cell following their concentration gradient. The  $Ca^{++}$  bind to proteins that attach neurotransmitter-containing vesicles to the membrane of the terminal button. A conformational change occurs in the proteins so that they pull and fuse the vesicles to the membrane, allowing neurotransmitters to be released into the synaptic cleft. This process is known as exocytosis (Llinas et al. 1981).

### Neuromuscular

Termination of an action potential can also have different physiological effects. In a neuromuscular junction, the action potential of a motor neuron will elicit the contraction of a muscle fiber. In this case, the neurotransmitter released by the presynaptic cell is acetylcholine, or Ach. The muscle cell contains sodium and calcium ion channels that have an Ach receptor. When it binds, these channels open causing the ions to rush into the cell. Inside the cell, the calcium binds to receptors in the sarcoplasmic reticulum, which contains a

large supply of calcium ions. This action causes the release of the ions which spread from cell to cell and fiber to fiber causing the muscle to contract (Lodish et al. 2000).

## Synonyms

Time budget

## Definition

A tool used to quantify what an animal does during the period of observation.

## Introduction

An important component of studying animal behavior is to establish an activity budget for the

species of interest. An activity (or time) budget quantifies what an animal does during the period of observation. It is typically constructed either by recording the duration of an animal's various behaviors for a set amount of time or by sampling at regular intervals what an animal or a group of animals is doing over a longer period of time. The method chosen is determined by the question the researcher wants to answer and the type of behaviors that are to be observed. Comparison of activity budgets within a species can reveal the effects of many different factors including age, sex, seasonal effects, and anthropogenic disturbances. Activity budgets can also be compared between captive and wild animals to help determine how behavior is affected by captivity. Changes in the distribution of behaviors or the occurrence of behaviors not seen in the wild can serve as important indicators about the health and welfare of captive animals. Activity budgets are a useful tool for conservation management.

## Constructing an Activity Budget

Activity budgets have been created for a variety of species representing invertebrates and all five vertebrate groups, amphibians, birds, fish, mammals, and reptiles. They are established in conjunction with an ethogram that describes the behaviors to be recorded and whether those behaviors are best classified as events (generally less than a few seconds in duration, such as a sneeze) or states (often persisting for minutes or hours, such as feeding or resting). A hypothetical activity budget is illustrated in Fig. 1.

Activity budgets conducted in the wild may vary substantially in the level of detail that can be recorded. The simplest type of budget is dichotomous, recording if the animal is moving or not. These types of budgets are generally compiled using technology to track free-ranging animals that move quickly through thick brush, treetops, or water which would be a challenge for researchers to follow on foot or with binoculars. In these cases, advances in technology using radio telemetry or GPS tracking collars equipped with accelerometers can yield binary information

**Activity Budget, Fig. 1** A hypothetical activity budget for three reindeer (*Rangifer tarandus*), Jarppi, Jarno, and Ronja. After data are collected, the percent of sample points that each behavior was observed can be calculated. For each individual animal, the scores across all of the behaviors should sum to 100%. In this example, individual

differences can be seen in the behavioral activities. Furthermore, these data reveal sex differences. The female, Ronja, was observed resting more often than the males and the males were more often observed standing and feeding. Only the males were observed engaged in agonism

about whether or not the subject is moving. For animals in captivity and those in the wild that can be more easily observed and tracked on foot, researchers are more likely to record a variety of behaviors. This can be done manually on paper, on a laptop or by voice recording, or by using devices such as smartphones and video cameras to record behavior continuously for subsequent analysis. Researchers log which behaviors are occurring using one of several standard sampling procedures.

Three sampling methods have been described in the literature (see Altmann 1974; Lehner 1998; Martin and Bateson 2007). In continuous (all-occurrences) sampling, the researcher records when a behavioral event occurred or the start and end time of a behavioral state. This method provides a largely unbiased representation of the frequency, latency, and duration of what an animal is doing throughout the observation period, although

it may underestimate the duration of long behavioral states that continue past the observation period. It is useful for studying sequences of behaviors but is not always practical because of constraints on the human observer. In fixed interval time point or instantaneous sampling, the observation period is divided into intervals of fixed duration (e.g., every 30 s or every 5 min; see Fig. 2). At the end of each sample interval (the sample point), the researcher records what the animal is doing. This procedure is less demanding on the researcher than continuous sampling but has the downside of underestimating the frequency of extremely rare or very brief behaviors. Conspicuous behaviors may also be overestimated because of a researcher's natural tendency to record such behaviors if they occur just before or just after the sample point. In one-zero sampling, the researcher simply records if a target behavior occurred at any point during the sample interval. This method may be acceptable

**Activity Budget, Fig. 2** A schematic of a fixed interval time point or instantaneous sampling procedure. The observation period is divided into intervals of equal duration. At the end of each interval (including the end of the observation period), there is a sample point. At each

sample point, the observer records the activity of the animal. The frequency that a behavior is observed with this sampling method is considered a good proxy for the time spent actually engaged in that behavior

for recording intermittent behaviors of short duration such as play. Researchers sometimes use multiple sampling methods in the same study in order to optimize accurate activity profiles.

### Activity Budgets in the Wild

Activity budgets are commonly used by researchers as part of their documentation of the natural history of a species and to answer questions about ecological and social influences on the behavior of a species. They have been important for showing that the time spent in different activities can vary both diurnally and seasonally within groups, between males and females, as a function of social rank and age, and between groups in different habitats. The impact of these variables on activity budgets can shed light on how animals maintain energy budgets. For example, food resources often fluctuate with seasonal variations requiring an adaptive response. King colobus (*Colobus polykomos*) monkeys appear to adopt an energy conservation strategy, spending more time resting and less time feeding when preferred seeds are not available. On the other hand, Yunnan snub-nosed monkeys (*Rhinopithecus bieti*) appear to adopt an energy-maximizing strategy, foraging more in the resource-poor season.

Numerous studies have reported diurnal and seasonal effects on activity. Beltramino et al. (2019) inferred activity budgets for the sedentary

Argentine sea bass (*Acanthistius patachonicus*) using algorithms to parse information from accelerometer data loggers. They found that active behaviors in the sea bass in the northern Patagonian gulfs of Argentina were on average 50% higher during the warm water season (16–18 °C) than during the cold water season (8–10 °C). In a study of a group of François' langurs (*Trachypithecus francoisi*) at the Nonggang Nature Reserve, Guangxi Province, China, diurnal activity revealed morning and afternoon peaks in feeding behavior with a midday resting peak (Zhou et al. 2007). Using instantaneous sampling (15 min fixed interval), the researchers also found seasonal effects on feeding activity with two significant peaks (morning and afternoon) in the dry season but only the afternoon peak in the rainy season. This difference may be related to seasonal variations in food sources and temperature although the authors do not rule out a measurement artifact that obscured a morning feeding peak in the rainy season. Age differences were also observed in this study with adults spending more time resting, feeding, and grooming and immatures spending more time playing.

The effects of sex, age class, and social rank on activity budgets have also been widely examined. One study used radio telemetry to record daily activity budgets of 26 South Georgia shags (*Phalacrocorax georgianus*) during the chick-rearing period at Bird Island, South Georgia. Two sexually distinguishable foraging patterns

were observed; males spent more time flying and on the sea and, in 93% of the pairs, the female was the first to leave the nest each day to search for food. Another study compared activity budgets for parent, nonparent, and juvenile wintering common cranes (*Grus grus*). In the period following arrival at the wintering grounds when still dependent on their parents, juveniles spent more time feeding and less time alert and preening than adult birds. This difference later disappeared when most of the juveniles reached parental independence. This study also compared parents and nonparents to determine potential costs and benefits of parental care. Although parents were more vigilant (higher rates of scanning) and spent less time feeding and resting than nonparents, there was no apparent cost as their net and absolute food intake rates were higher than those of nonparent adults. The effect of social rank on vigilance behavior in rutting ungulates has yielded discrepant findings. A study of territorial male impala (*Aepyceros melampus*) found they allocated more time to vigilance against intruding rivals. However, a study of elk (*Cervus elaphus*) found that rutting bulls engaged in courtship spent little time being vigilant. This pattern suggests that, in ungulates, variations in vigilance during rutting may reflect an interaction between social rank and species-specific mating systems rather than social rank per se.

Isbell and Young (1993) used activity budgets to examine the effects of sex, rank, habitat, and group size in six groups of vervet monkeys (*Cercopithecus aethiops*) living in Amboseli National Park, Kenya. Over a period of 20 months between June 1986 and January 1988, they calculated the average time that monkeys spent on feeding, moving, resting, scanning, allogrooming, or other (social and nonsocial) activities. Overall, males scanned more than females and dominants scanned more than subordinates. Scanning may be used to monitor for predators or to check on potential competitors for food or mates. Habitat effects were observed on two behaviors. Briefly, vervet monkeys spent more time moving and allogrooming in the *Acacia xanthophloea* habitat than the monkeys in the *A. tortilis* habitat. The difference in moving is consistent with differences in

resource distribution and food abundance between the two habitats. The researchers suggested that the influence of habitat on allogrooming might reflect differences either in ectoparasite density or in group size. The groups in *A. xanthophloea* were larger than the groups in *A. tortilis*, and allogrooming was positively correlated with group size.

### Activity Budgets in Captivity

Activity budgets are frequently used to assess animal welfare in captive settings. Captive environments are often designed to elicit natural behavior or behavior that resembles that of the animal's wild counterparts. Animals in the wild spend much of their activity budget on survival needs, like finding food and mates. These needs are often not present for captive animals, where food is provisioned and mating is controlled. Given that many animals have adaptations to help serve these needs, and not performing them can impact both the mental and physical health of the animals, there is great interest in understanding how closely captive animals' activity budgets resemble their wild counterparts.

Historically this was done by a direct comparison – constructing an activity budget in a captive species and comparing it to that same species in the wild. For example, Veasey et al. (1996) compared the activity budget of giraffes (*Giraffa camelopardalis*) in four zoos to those found in the wild. They found significant differences in the amount of time the giraffes spent feeding, ruminating, standing, and engaging in stereotypical behavior. Interestingly, although occurring at significantly lower rates, stereotypical behavior was not absent in the wild giraffes, showing that it may not be an abnormal manifestation of life in captivity. However, the authors suggest that the differences in the activity budgets did not arise from behavioral restriction in captivity but rather from observation methods. Despite taking care to closely replicate the same methods in captivity and the wild, they noted that the presence of observers had a larger impact on giraffe behavior in the wild versus in captivity, and certain

behaviors like stereotypies might be more visible with the closer distances and unobstructed viewing allowed by captivity. Furthermore, they noted that the four different methods they used to observe the giraffes in the wild (ranging from following them in a four-wheel drive vehicle to approaching them on foot) resulted in dramatically different activity budgets, suggesting that a wild study using a single method might not be representative of the species' full behavioral repertoire.

In general, there are numerous differences in data collection methods that can impact the comparability of field and captive data. With the advent of new accelerometer technology that can be used across settings and reduce the need for observers to collect data in person, there is potential for more accurate comparisons. However, differences in behavior observed from captive to wild would still require critical interpretation. In the giraffe study, the giraffes with the best enclosure, a large, grassy paddock, spent the most time grazing and lying down (Veasey et al. 1996). These two behaviors are less possible in wild giraffes, since the dry season limits grazing and lying down increases predation risk. In other words, when they have the choice, giraffes choose to rest more, suggesting that the decreased activity seen in captivity may not reflect a welfare problem.

In recent years, a desire to better understand the impact of activity on captive animal welfare has led to a different approach, using activity budgets to study behavioral diversity, which is a measure of the number of different behaviors an animal performs (the richness of their behavior) combined with the frequency of different types of behavior (Miller et al. 2020). It is thought that if an animal exhibits high behavioral diversity, they are using more of their natural adaptations and are appropriately mentally stimulated. This inference is supported by data across species showing that as behavioral diversity increases, stress hormones, such as glucocorticoids, decrease.

Behavioral diversity can be assessed by constructing an activity budget and examining both the number of different behaviors exhibited by an individual and the frequency with which they perform those different behaviors. Behaviors

included in this analysis should only consist of those relating to positive welfare (Miller et al. 2020). Although certain behaviors such as stereotypical behaviors or aggression are certainly part of an animal's activity budget, and large amounts of time spent in these behaviors should elicit concern, it is helpful to understand how much of an animal's time is devoted to positive behaviors. The activity budget data can also be used to calculate a behavioral diversity index, the most famous of which is the Shannon-Weiner index. These indices combine all of the different types of behavior into an overall value that reflects the variety and frequency of behaviors an individual is performing. Behavioral diversity indices can be useful for comparing activity budgets across individuals and different institutions.

## Conclusion and Future Directions

Activity budgets have long been used to better understand the activity patterns of animals in the wild and how those patterns are influenced by ecological and social factors. Such information has proven crucial for assessing the potential impact of anthropogenic disturbances and for conservation management of endangered and threatened species. In a study of the North Atlantic population of minke whales (*Balaenoptera acutorostrata*), a mysticete, on one of their feeding grounds (Faxaflói Bay, Iceland), Christiansen et al. (2013) used a biologically based modeling approach to construct activity budgets to demonstrate that whale watching boat interactions resulted in a 42% decrease in overall feeding activity. Such short-term behavioral disruptions warrant further analysis as they may have a cumulative impact on vital rate measures (survival, growth, and reproduction) that could influence species fitness. In another study, continuous recording of the Sri Lankan endemic shrub frog *Pseudophilautus popularis* in a wetland-home garden setting in an urban area revealed that the height at which male frogs perch on leaves and branches to call gradually increases from about 15 cm around dusk to a maximum of 180 cm above ground level by 2300 h and then, after

about 2 h, gradually decreases toward dawn (Dayananda and Wickramasinghe 2014). These findings underscore the importance of biodiversity in vegetation stratification to maintain a habitat that will support the conservation of this species.

Activity budgets can also be used to assess changes to a captive animal's environment and the impact of welfare interventions. For example, a review of 28 studies revealed that in 78.6% of them, behavioral diversity increased following the provision of enrichment or some other enhancement to the enclosure (Miller et al. 2020). Likewise, a decrease in behavioral diversity, or increase in abnormal behaviors or inactivity, could signal a welfare problem that needs attention. Regular monitoring of captive animals' activity budgets is crucial to their well-being. This can be a challenge not only in terms of cost and labor but in sustaining unbiased and consistent observations. The use of automated electronic surveillance systems and behavioral recognition software may well help alleviate such problems.

Recent advances in technology have played an important role in improving the quality and accuracy of activity budgets for both wild and captive animals. Hertz et al. (1988) suggested that the perplexing problem of why taxonomically diverse reptiles do not routinely use their maximal capacities for locomotion might well be solved by attaching accelerometers to lizards for long-term monitoring of activity in response to rare events. The use of increasingly sophisticated accelerometer devices coupled with machine learning algorithms and visual authentication of behavior are only likely to strengthen the unbiased comparisons that can be made between wild and captive activity budgets. Finally, for both wild and captive animals, changes in activity budgets must be assessed before and after human interactions or interventions, to better understand and manage the impacts humans are having on other species.

 (UNED), Madrid, Spain

## Synonyms

Activity anorexia; Activity-induced anorexia;  
 Self-starvation; Semi-starvation-induced hyper-  
 activity (SIH)

## Definition

Activity-based anorexia (ABA) is a robust phenomenon that takes place in many animal species in which excessive physical activity is developed to a deleterious level when access to food intake is restricted to a short period of time a day (e.g., 1–2 h), resulting in reduced eating and substantial body weight loss. Paradoxically, the increment in locomotor activity takes place when energetic balance is negative, so that continued exposition of an animal (usually rats or mice) to intermittent food delivery plus almost permanent access to exercise could drive the animal to die if it is not withdrawn from the procedure. ABA constitutes the most recognized animal model of anorexia nervosa disease in humans due to the similarities between the behavior observed when animals are submitted in the laboratory to the above conditions and the characteristics of clinical patients suffering the disorder.

## Historical Background

The first scientific observations of the effect of long periods of starvation on different species of birds, reptiles, and mammals in the mid-nineteenth century by Charles Chossat (1843) reflected that, during much of the process, the animals remained to a greater or lesser extent in a state of agitation that lasted until the moments near before their death. Although those studies, which would hardly meet current ethical standards, detailed the physiological processes that took place in the animals, no significant importance was conferred to the high physical activity developed. It was not until the early twentieth century when the work of Richter (1922), sponsored under the direction of J.B. Watson, delved into the biological basis of spontaneous activity in laboratory rats, bringing to experimental study the locomotive behavior developed by the animals in constant conditions of light and temperature and introducing the use of boxes and running wheels to make precise measurements of the activity developed. In those experiments, it was revealed the existence of circadian rhythms in the activity of the subjects, as well as the concentration of this activity around the meal period when it was supplied once a day, among other observations of the factors that influence the level of activity and that are still valid today, such as the sex of the animal or the ambient temperature.

However, the systematization of studies on the failure of maintaining stable weight in rats living in activity wheels under a food deprivation schedule has its milestone in the work of Routtenberg and Kuznesof (1967), who named the phenomenon “self-starvation.” Those authors introduced a control group, with the same food schedule but without access to the running wheel, that ate more and stabilized its loss in weight compared with the activity group who “self-starved” and died.

In the 1980s of the twentieth century, the influential work of Epling, Pierce, and Stefan (1983) highlighted the importance of locomotor activity in times of food shortage in the phylogeny of species as a form of survival, relating the behavior observed in the laboratory animals with that developed in many cases of anorexia nervosa in

humans. These instances were called activity-based anorexia, linking since then the study of its causes and the development of treatments for this disorder to a valid animal model given that it reproduces many of the characteristics present in the anorexic patients.

## Experimental Protocol

The basic ABA protocol includes the use of two groups of animals, usually named Active and Sedentary, or simply ABA and FR (food restricted). The procedure in the ABA (Active) group starts with the removal of food and

allowance of free access to a running wheel for 23 h before the next meal opportunity (see Fig. 1). This day is known as day 0, and the weight data obtained prior to food restriction is the initial weight against which its loss is calculated the remainder days. Animals in the ABA group usually have 1–2 h food exposition and 22–23 h of wheel access each subsequent day until the end of the procedure. In order to prevent death and reduce animal suffering, each subject is removed from the procedure when reaching 20–25% of weight loss for two consecutive days. Animals in FR (Sedentary) group are subjected to the same food restriction schedule but without access to the running wheel. All animals

### Activity-Based Anorexia,

**Fig. 1** Images showing a home cage with attached activity wheel that can be used to run the activity-based anorexia (ABA) procedure in the laboratory with rats

**Activity-Based Anorexia, Fig. 2** Expected results in weight loss during ABA procedure

**Activity-Based Anorexia, Fig. 3** Expected results in wheel running during ABA procedure

in both groups are weighed each day before the meal period. As seen in Fig. 2, FR animals (dotted line) show initial reduction in body weight and then stabilization around 85% of their free-feeding weights. However, ABA animals (straight line) fail to maintain their weights and progress with a dramatic reduction. Accompanying weight loss, ABA animals show a gradual increase of running along the days in the procedure (Fig. 3, straight line). Comparing both groups, it can be suggested that weight loss relates to the increased activity expressed in ABA animals. It can be added an optional extra control group for activity (unrestricted); here animals are maintained in ad libitum food schedule and have the same time access to a running wheel than ABA animals. In this case, animals do not show the excessiveness in activity observed in the ABA group (Fig. 3, dotted line). These results suggest that the increase in activity relates to the food schedule. See Carrera, Fraga, Pellón, and Gutiérrez (2014) for an extensive description of the protocol.

## Main Interpretations

Regarding the hypotheses to explain ABA, they can be grouped in two: those that focus on food

consumption and those that suggest a central role for activity.

Within the first group, authors (e.g., Kanarek and Collier 1983) suggest that running interferes with the adaptation to the meal schedule preventing ABA animals from maintaining their weights, while the subjects in the control group with same food exposition but with lack of access to a running wheel can maintain their weights. Results have shown that prior exposure to the food schedule causes retardation in the development of ABA, but it does not prevent it (Lett et al. 2001).

Within the group of authors that give a crucial role to activity, there are theories that suggest that wheel running is linked to foraging behavior. Animals increase their activity during shortages of food as a natural selection mechanism to search for alternative sources, activity being possibly induced by the intermittency of food occurrence (Epling et al. 1983). The fact that the intensity of wheel running frequently increases in anticipation to food when it is given periodically (Bolles and Moot 1973) suggests that running is maintained by its consequences as it is explicitly operant running or another schedule-induced behavior. It is well documented that ABA animals distribute their running in two peaks around food occurrence, just before and immediately after meal, according to the control exerted by food availability.

## Influencing Factors

There are some factors that are involved in the vulnerability or resistance to ABA. As commented before, prior exposure to the feeding schedule retards the development of ABA. On the contrary, prior exposure to a running wheel facilitates its development. It is known that high ambient temperature prevents the phenomenon. Regarding individual variables, older and heavier rats are more resistant than young and light rats to develop ABA. In the case of sex differences, there are conflicting results, but data seems to point a greater vulnerability to ABA of female rats. Factors that could increase stress, such as social isolation or early maternal separation, contribute to a greater vulnerability; however, environmental isolation (e.g., sound of other animals running) can prevent excessive activity. Early handling experience also reduces the vulnerability to ABA. Some studies have found that ABA can be developed with only 2–4 h of wheel running access per day, mainly those in proximity to next food availability (a phenomenon known as food-anticipatory activity – FAA). Other modulating factors are related to the type of food used (e.g., its dryness or quality).

## Neurobiological Basis

The ABA model has not only been applied for the analysis of environmental and individual variables that influence the phenomenon and/or the study of the functional relationships established between starvation and hyperactivity during its development. In recent decades, it has been used to try to unravel neurobiological and physiological aspects involved, as well as possible vulnerabilities. The ABA protocol allows the control of psychosocial variables that are difficult to isolate in studies of this sort carried out with clinical patients. In these experiments there have been used different strains of rats and mice with specific phenotypic characteristics or genetically modified for a gene that encodes both central and peripheral substances, or receptors, that regulate feeding and/or physical activity. These subjects are

submitted to the ABA conditions (i.e., restricted food delivery and free access to a running wheel) allowing the identification and understanding of the biological substrates and processes that drive behavioral characteristics exhibited along the procedure under tightly controlled conditions.

Research has pointed out the involvement of the gut-brain axis in reduced food consumption and development of overactivity in ABA. Peripheral orexinergic signal of ghrelin gut hormone, that induces appetite, and the circulating level of leptin, as a satiety signal informing about adipose tissue reserves, are detected in the brain level through the brain stem afferences to hypothalamus, considered a central regulator of feeding behavior. These hormones influence two populations of neurons located in the arcuate nucleus (Arc), the effects of which are antagonistic respect feeding behavior. While the orexinergic group of neurons are activated by ghrelin and promote ingestion, proopiomelanocortin (POMC) system neurons are activated by leptin, secreting anorexigenic substances that inhibit food consumption. Both leptin and ghrelin are implicated in the development of excessive physical activity during starvation, while ghrelin has been specifically associated with anticipatory activity developed when food is supplied under fixed interval schedules. An imbalance of these peptides along the progression of ABA, and their interaction with dopamine projections in the mesolimbic reward pathway, could account for the aberrant rewarding properties of food and physical activity and contribute to the development and maintenance of the process (see Adan and Kaye 2011, for a review). Drugs that exert control over dopamine, key neurotransmitter in reward and motivational systems, and regulatory central neurotransmitter serotonin, mainly antidepressants and antipsychotics, also have been profusely investigated as targets of possible pharmacological treatments.

Other structures and pathways that have been studied as associated with the hallmarks of ABA are cortico-striatal neuro-circuitry, hypothalamic-pituitary-adrenal (HPA) axis, other structures in the limbic system, as hippocampus or amygdala, or the endocannabinoid system (Schalla and Stengel 2019).

## Conclusion

Activity-based anorexia is a good animal model of human anorexia nervosa, and the investigation of the behavioral and neurobiological mechanisms involved will help in better understanding the disorder and the development of more efficacious interventions.

## Adam Miklosi

Ádám Miklósi

Eötvös Loránd University, Budapest, Hungary

**Ádám Miklósi, PhD**, is a Professor of Ethology at the Eötvös Loránd University in Budapest. He participates in editorial boards of several journals including *Animal Cognition*, *Applied Animal Behavior Science*, and *Frontiers of Psychology*. His interests are in animal cognition with particular focus on communication and social learning. More recently he became interested in animal-robot interaction and started an interdisciplinary new approach called ethorobotics.

### Early Life and Educational Background

Dr. Miklósi was born September 25, 1962, in Budapest, Hungary. Adam grew up in Budapest, the capital city of Hungary, and was determined to become a biologist already by the end of the elementary school. He started undergraduate studies in 1981 following 4 years in a secondary school and 1 year spent at the Hungarian Defense Force in obligatory service. He graduated in 1986 from the Eötvös Loránd University as a biologist

### Professional Career

Adam Miklósi received a fellowship from the Hungarian Academy of Sciences for 3 years during which he started his research carrier at the Laboratory of Behaviour Genetics at Eötvös Loránd University. Subsequently, he became an associate professor at the newly formed Department of Ethology at the same university. He received his PhD in 1995 for studying the learning mechanisms of predator avoidance in the paradise fish. Starting in 1997, he spent 2.5 years in England at Sussex University supported

by a Royal Society Research Grant and a fellowship from the Wellcome Trust (Barth et al. 2005). After returning to Hungary he became reader, and in 2006, he was appointed as a head of department. He defended his thesis and received the degree of “Doctor of Sciences” in 2006 by the Hungarian Academy of Sciences. In 2011 he was promoted to full professor and was elected a corresponding member of Hungarian Academy of Sciences.

In 2003, he received a Frank A. Beach Comparative Psychology Award (best paper of the year) and, in 2010, the Distinguished Scholar Award from the International Association of Human-Animal Interaction Organisations (IAHAIO). For his outstanding contribution to teaching, the Eötvös Loránd University awarded him the Medal for the Scientific Education of Biology Students, and the Juhász-Nagy Pál Prize for assisting in biology student competitions. In 2015, the Hungarian Academy of Sciences honored him with the Prize of the Hungarian Academy for research achievements. He is a member of the Hungarian Biological Society (from 1988) and the Hungarian Ethological Society (from 1991). He is also a member of the board of trustees of the Dogs for Humans charity. This organization facilitates the education of dog handlers and also trains dogs for the disabled.

He participated in several large-scale international research consortiums supported by the European Union. One of these studied the evolution of referential communication, the other investigated possibilities of human-robot interaction from an ethological point of view. From 2008 to 2012, he was chair of an ESF (European Science Foundation) Research Networking Program titled “The Evolution of Social Cognition: Comparisons and integration across a wide range of human and non-human animal species.” This program coordinated the work of 28 different research organizations working in the field of comparative cognition.

As of 2017 he is the author of 166 papers published in scientific peer-reviewed journals, his Hirsch index is 38.

## Research Interests

Miklósi is the co-founder and leader of the *Family Dog Project* (<http://familydogproject.elte.hu>), which aims to study human-dog interaction from an ethological perspective. The process of domestication put dogs into a unique relationship with humans because they gained skills that allow specific behavioral adjustments in the human social environment (Gácsi et al. 2009; Lakatos et al. 2009; Miklósi and Topál 2013; Topál et al. 2009a, b). Miklósi and his collaborators showed that dogs develop specific attachment relationships with their owners, dogs are able to communicate with humans using a range of fine-tuned visual and acoustic signals (Lakatos et al. 2009; Téglás et al. 2012), and dogs are also able to learn via observation and utilize such knowledge for their own benefit. In recent years, he became interested also in the automatization of measuring dog behavior and looking at ways to study the neural and genetic aspects of dog behavior using non-invasive methods (Andics et al. 2014, 2016; Héjjas et al. 2009; Kis et al. 2014).

Miklósi and his team worked out the concept of ethorobotics – an area at the cross road of robotic engineering and ethology – the main goal of which is to build functionally relevant robots that fit in the anthropogenic environment and are able to interact socially with humans similarly as other animal species. He is also studying animal-robot interaction in order to find out what kind of challenges should a robot overcome to become a social partner of animals, and also to use the robot as a stimulus to study the mental representation of the “other” in animals, especially dogs.

Over more than 20 years The *Family Dog Project* published more than 150 scientific papers, and organized several conferences. In 2008 researchers and experts gathered for the first time in Budapest and started the conferences series of Canine Science Forum (<http://csf2008.elte.hu>) to share their results and insights on dogs and their relationship with humans.

In 2014 he published the second edition of an academic volume entitled *Dog Behavior, Evolution and Cognition* by Oxford University Press

that summarizes the most recent status on dog-oriented research (Miklósi 2007).

## Synonyms

Behavioral adaptations; Environment; Evolution;  
Fitness; Physiological adaptations; Structural  
adaptations; Survival

## Definition

Adaptation can be defined as alterations/changes in physiological, behavioral, and structural characters of an individual in response to their environment.

## Introduction

Adaptation consists of Latin words *ad* (“toward”) plus *aptus* (“fit for some role”); any structural, physiological, or behavioral character that increases organism’s survival fitness as well as their reproduction ability in existing environment. In other words, adaptation is the ability of any living organism to survive and reproduce successfully under the existing environment.

Adapted organisms are more fit because they are (1) able to secure food and nutrients; (2) able to obtain air and water; (3) secure spaces in niche; (4) cope with physical conditions such as temperature, light, and heat; (5) defend themselves from their predators; (6) reproduce and rear offspring; and (7) quickly respond to changed environment.

## Historical Background

Up until the middle of eighteenth century, scientists generally believed that various living forms have existed in this universe without undergoing any change and will remain unchanged in future also. Many features of living organisms like the bee’s sting, the vertebrate (an animal with a backbone), and the human brain have been created by a supernatural power to serve their specific purpose. A philosophy known as “theory of special creation or creationism.”

But at end of the eighteenth century, the scientific community started noticing the morphological similarities occur in plants and animals of different periods in earth, existence of many connecting links between species of different periods, increasing complexity of structure in both plants and animals through geological periods, and prompted a new idea that living organisms on earth developed gradually and unevenly from simple to advanced organisms. New species develop due to modifications in preexisting forms. Such modification occurs in any species due to changed environmental conditions, and organisms need to adapt themselves according to its new environment to survive.

## Factors Affecting Adaptation

Most organisms have different dimensions of adaptation and should interact to different aspects of their environments simultaneously. Adaptation involves coping with both physical/abiotic environmental factors (light, dark, temperature, water, and wind) and complex biotic environmental factors (other organisms such as mates, competitors, parasites, predators, and escape tactics of prey). Adaptation mainly occurs due to changes in the environmental conditions, life cycle pattern, or relationship with organisms. All changes in environmental conditions and human activities may cause shifting of organisms in a new niche or in environmental stresses or pressures. In such conditions, those organisms survive successfully that develop suitable characteristics according to the new situation. Organisms that are not suitably

adapted to new environment will either have to move out or die, sometimes result in the disappearance of entire species. This is known as “Natural Selection” (Pianka 2000).

In 1859, Charles Darwin (1809–1882), the great English naturalist, published his famous book *The Origin of Species by Means of Natural Selection*. In this book, Darwin discusses adaptation of organisms as the product of natural selection. Natural selection implies that – when forced to compete for limited resources such as food – those organisms best adapted to their specific environment are most likely to survive, reproduce, and transmit their traits to offspring.

Adaptation and acclimation (acclimatization) are entirely different phenomenon. Adaptation is a phenomenon that occurs in population. The process of developing adaptations occurs over many generations, generally a slow process. Acclimation or acclimatization, on the other hand, generally involves single lifetime or develops instantly and deals with issues that are less threatening. For example, when we move to a higher altitude, respiration and physical exertion will become a problem due to low O<sub>2</sub> pressure. However, after spending a period of time under the high altitude conditions, one may acclimatize to the reduced O<sub>2</sub> pressure (Shukla and Chandel 1996).

## Types of Adaptations

All organisms including plants, animals, and microbes live in different environments like drier, hotter, colder, more acidic, saline, darker, sunnier, etc. Different genetic methods, such as mutation and genetic recombination, are helpful in the survival of these organisms, when any type of modifications/changes occurs in these habitats. These changes pass down to offsprings and become prevalent in the population as an adaptation. The three basic types of adaptations, based on how the genetic changes are expressed, are structural, physiological, and behavioral adaptations. Most organisms have combinations of all these types.

## Structural Adaptations

All adaptations that involve some part of plant/animal, such as the size or shape of the teeth, which is covered by the animal’s body, are known as structural adaptations.

### Type of Teeth

The number, size, shape, and location of teeth and the movement of the jaw differ in mammals according to the type of food they eat. The number and type of teeth also reveal about diet and feeding methods of animals. For example, carnivore (like cougar) has long canines that are used to bite and tear the prey. On other hand, herbivore (like beaver) lacks canines and uses its long incisors to strip bark and gnaw wood.

For example, variations in structural features of bird beaks are an important adaptation which greatly depends on type of the food and how it is obtained. For example, woodpeckers have long, tough, pointed beaks, along with a very robust skull that allows them to hammer holes in trees in search of food. Hooked beaks can be used for biting and stripping (similar to mammal’s incisors), whereas long slender beaks can be used to gather nectar from flowers, as in humming birds. Thin beaks are generally useful for manipulating prey, like caterpillars. Wide beaks are useful for catching flying prey, like mosquitoes. Other variations observed in beaks include serrated edges for holding prey (like fish) (Fig. 1).

### Body Coverings

Hair, scales, spines, and feathers grow from the skin. All of these parts help animals survive in their environments.

For example animals living in a hot dry environment like the chaparral biome manage their internal temperature with large areas of exposed skin with little internal volume such as tails, legs, or ears. The black-tailed jackrabbit has extremely large ears, approximately one third of its body in length. Dozens of small blood vessels present in large ears which expand when the animal is hot, allowing more quantities of blood to flow through the ears and be exposed to the external environment, cooling the blood as it moves. When

**Adaptation, Fig. 1** Types of beaks

external environment is cool, the blood vessels constrict, lessening the amount of blood that passes through the ears. Jackrabbit can very efficiently maintain its internal body temperature with this adaptation (Schmidt-Nielsen 1972). Other desert mammals, such as foxes, rabbits, mice, and rodents, also possess this adaptation (<https://chaparralbiomedexter.weebly.com>).

Another example is an ostrich (animal with a specialized coat) which has no feathers on its head, neck, and legs but a fluffy coat of feathers on its back and abdomen. The lack of feathers allows heat to more efficiently escape and the thick coat of feathers protects the ostrich's back from the sun.

Plants adapt themselves to hot climates in a number of ways. Plants maintain their water levels and minimize water loss mostly through structural adaptations such as small waxy leaves with a thick cuticle, the reduced size allows for less sun exposure, and the waxy layer over a thick cuticle ensures little water escapes through transpiration. Leaves of these plants typically possess few stomata or leaves reduced to spines and stem is the

main photosynthetic organ because the leaves are unable to perform photosynthesis, e.g., *Opuntia*. Many xerophytic plants (desert and arid plants) are adapted to capture and store water. During the rare rains in the desert, they absorb as much of water as possible and store, e.g., *Cacti*, *Opuntia*, *Agaves*, and *Euphorbias* (cactus-like plants). These plants will store water in their stems, leaves, or trunks, known as “succulent” (Fig. 2).

The sand lizard (*Moloch*) and horned toad (*Phrynosoma*) have hygroscopic skin to absorb moisture. Desert animals prevent water loss from their body by different mechanism like making skin impermeable by thickening and hardening as well as through the presence of scales and spines (*Phrynosoma*, *Moloch*), reducing the number of sweat glands in mammals and becoming active at night (nocturnal). Animals like polar bears, penguins, Arctic fox, etc. living in coldest habitats on earth like Antarctica, Arctic, and Alpine regions have thick fur, and layer of fat skin helps in insulation and to keep warm. Also they have well-curved and sharp claws that support them in walking on ice (Fig. 3).

#### Camouflage/Mimicry

Many animals have the ability to blend with surrounding environment in order to avoid a predator, e.g., scorpion fish and leaf frogs can change their appearance to match their surroundings. Polar bears, penguins, Arctic fox, etc. have snowy white fur to camouflage them and protect from predators. Many forest animals have striped or spotted appearance similar to leaves, and desert animals may be sandy colored. The chameleon has the ability to change its colors according to the color of the surroundings as it has several layers and varieties of chromatophores.

#### Physiological Adaptations

Physiological adaptations are related to changes in the chemistry and metabolism of different organisms and are usually not visible. Animals in the desert like kangaroo rats have very concentrated urine which means little to no water is wasted and the liquids can be reabsorbed back into the body of the animal.

**Adaptation, Fig. 2** Succulent plants (A: *Opuntia* B: *Euphorbia* sp.)

**Adaptation, Fig. 3** Cold habitat animal (A: Emperor penguin B: Polar bear)

Deserts are the dry and hot regions; plants and animals have different adaptations like, they can save water in the form of body fat in structures like hump (e.g., camels) or have short body structure like ear and tails to maintain the body temperature and to reduce water loss (e.g., fox) (Fig. 4). In hot and dry climates, an alternative

pathway, i.e., Crassulacean acid metabolism (CAM) for photosynthesis is operated where water loss is reduced by keeping the stomata closed during the day. During night,  $\text{CO}_2$  absorbed and stored in vacuoles through open stomata and converted to energy by photosynthesis during the day.

A

**Adaptation, Fig. 4** Desert animals (A: Camel B: Fennec fox)

### Behavioral Adaptations

Any adaptation that affects an animal's actions are called behavioral adaptations. These may include what an animal can eat, how they mate, or how they protect themselves.

#### Hibernation

Hibernation is one of the several ways for survival of animals in extreme cold winters. Hibernation involves certain changes in animals such as decrease in body temperature, slow breathing, and reduced metabolic rate. Squirrels, woodchucks, and chipmunks are able to hibernate for up to 12 months. Several other animals that hibernate are bears, bats, skunks, bees, snakes, and groundhogs.

#### Movement/Migration

It is a behavioral adaptation that involves an animal or group of animals moving from one place to another and then back again. Animals move for the following reasons: (a) to get more suitable environment; (b) to get food; (c) to get safe place to mate and raise their offsprings.

#### Nest Parasitism

Some birds like cuckoo prefer to lay their eggs in the nests of other species, who then feed and take care for the cuckoos' orphaned offspring. This feature is known as nest parasitism (<http://www.animalplanet.com/wild-animals>).

### Current Approaches to Adaptation

Charles Darwin was the first to postulate the central role of adaptation in evolution. There is a big gap in our understanding about adaptive traits and their underlying molecular bases. Ronald Fisher was the first to explain this topic theoretically by his "geometric model" of phenotypic change and adaptation (Fisher 1930). According to Fisher, probability of a mutation to be adaptive is nearly 50% for mutations of infinitesimally small effects and approximately zero for mutations of very large effects. Fisher also mentions that minor effect mutations are more likely to be beneficial compared to major effect mutations, but less likely to fix in a population.

Recent models of genetic basis of adaptation are mainly focused on DNA or protein sequence evolution. These studies have provided evidence for a small number of sequence changes occurring during the adaptive evolution of a gene (Gillespie 1991), as well as support for large relative fitness increases after the substitution of a beneficial mutation (Orr 1998). These studies also suggest that major effect mutations may be important to adaptive evolution.

Some researchers make a distinction between current use and the historical origin of adaptive traits. This distinction has led some researchers

(Stephen Jay Gould and Elisabeth Vrba) to suggest a different term “exaptation” to describe traits that were originally intended to perform different functions in an organism. For example, white coat of snowshoe hare helps them to camouflage in the snow and does not provide information about the origin of the species of white fur. It may have evolved for its improved heating properties and only by chance proved to be advantageous as camouflage. Therefore, sometimes the features we treat them as adaptive are really only secondary uses of traits that originally arose for other reasons.

## Conclusion/Summary

Living organisms inhabit in different ecosystems or natural environments which present a variety of biotic and abiotic stresses. (1) Adaptation is an evolutionary process through which a species becomes more fit to live in challenging environments. (2) Every adapted species possess some unique adaptive character that may be structural, behavioral, and physiological or can involve life-history parameters.

Structural adaptations involve some morphological features of an organism (e.g., size or shape of the teeth). Behavioral adaptations affect animal's actions to increase its survival and reproduction fitness (e.g., unique lekking behavior in different morphs of male ruff allows them to increased access to females for mating). Physiological adaptation comprises of the response of a species to a particular stimulus (e.g., many xerophytes has sunken stomata to reduce water loss by transpiration). Adaptive evolution is driven by natural selection and is one of the important processes that explain the diversity of life.

## Adaptedness of Behavior

Ulrika Candolin

University of Helsinki, Helsinki, Finland

### Synonyms

Adaptation; Adaptive behavior; Behavioral accommodation; Behavioral plasticity; Fitness

### Definition

The adaptedness of behavior depends on the effects behavior has on individual fitness, i.e., how it influences survival and reproductive success. This hinges in turn on how well suited to environmental conditions the behaviors are.

### Introduction

Behavior is a major determinant of fitness. It influences foraging success, the ability to avoid predators, success in the competition for resources, and reproductive success. Similarly to other traits, behavior evolves through natural selection; individuals with behaviors that allow them to produce more viable offspring than other individuals pass more copies of their genes onto the next generations, and thereby also the genes for their behaviors, which then increase in frequency in the population.

Evolution consequently gradually changes the behavior of individuals so that they become better and better adapted to local environmental conditions; lions have evolved a hunting strategy that is efficient in the catching of prey on the savannah, while their prey have evolved escape strategies that increase their possibility of escape in the same habitat. This dependency on environmental conditions implies that changes in the environment can reduce the adaptive value of behaviors (Candolin and Wong 2012; Wong and

Candolin 2015). For instance, newly hatched sea turtles use the moonlight reflecting off the ocean to find their way from the beach to the sea. However, artificial lighting from roads and cities is currently disorienting the turtles, which, instead of heading toward the sea, are drawn toward the land. Here, dangerous roads take their toll, and land predators, such as foxes, dogs, and birds, further decimate the population, while the hatchlings that escape these hazards may eventually die from dehydration. Thus, the behaviors that have evolved under past, natural conditions are maladaptive in human-altered environments.

The degree to which behaviors are sensitive to changes in the environment, and the extent to which they remain adaptive or not, depends on their plasticity (or robustness) and on the possibility of evolutionary changes. In the following, I will discuss why behaviors are sensitive to environmental conditions, how they can be altered through plastic responses and evolutionary changes to become better suited to prevailing conditions, and why individuals in a population often differ in their behaviors.

### Dependence on Environmental Conditions

The behavior that an animal adopts in a particular environment depends on its behavioral reaction norm (or response curve), in other words, on the behaviors that a particular genotype expresses across a range of environments (Tuomainen and Candolin 2011; Sih 2013). For instance, the behavioral reaction norm of an animal can induce it to increase its food intake when temperature rises or to spend less time searching for food when it rains. Thus, reaction norms determine how animals adjust their behavior to variation in the environment. The norms have been shaped by past evolutionary processes and have a genetic basis. They can evolve across generations, similarly to other traits, as well as change during the life span through environmental and epigenetic effects, including parental effects (Fig. 1).

**Adaptedness of Behavior, Fig. 1** Behaviors are determined by both genes and the environment. These determine the evolution of behavior and its degree of plasticity, which then influence the survival and reproductive success of individuals and, hence, their fitness

Because behavioral reaction norms have evolved in the past, under the conditions that then prevailed, they can be maladaptive under altered conditions. Thus, species that encounter conditions that they have not encountered in their recent evolutionary past may not have reaction norms suited to the altered conditions (Fig. 2). For instance, many animals have evolved migration strategies that are timed so that reproduction coincides with the peak availability of critical food resources for offspring. However, climate change is currently altering the phenology of food organisms, which is disrupting the timing between arrival at breeding grounds and food availability. An example is the long-distance migratory pied flycatcher (*Ficedula hypoleuca*) that migrates from overwintering sites in Africa to breeding grounds in Europe. The species rely on a short burst of caterpillar availability each spring to feed its young. However, the caterpillars have been emerging earlier as temperature in spring has risen. Because the flycatchers use their endogenous timing mechanisms to determine when to migrate, they have not been able to advance their arrival date to the same extent as spring has advanced at the breeding grounds. This

**Adaptedness of Behavior, Fig. 2** When the environment changes, animals respond to the changes according to their behavioral reaction norms, which have evolved under past environmental conditions. However, these may not be adaptive under the altered conditions but result in maladaptive behaviors. Evolutionary changes of behavioral reaction norms may be needed for individuals to behave adaptively in the new environment

has resulted in a phenological mismatch between the hatching of the nestlings and the availability of caterpillars (Both and Visser 2001).

When animals decide on the behavior to adopt in a given situation or environment, they generally use various cues to evaluate the environmental conditions. For instance, many animals in seasonal habitats use day length as a cue for when to start reproductive activities, such as defending a territory, building a nest, or attracting mates. These cues are usually reliable indicators of current conditions. However, when the environment suddenly changes, either naturally or because of human activities, the cues may become unreliable indicators of environmental conditions. For instance, artificial lighting along beaches does not indicate the position of the sea to newly hatched sea turtles. The earlier evolved behavioral strategy then becomes maladaptive and causes an “evolutionary traps,” with sea turtles orienting toward the artificial light on land. Other examples of evolutionary trap are aquatic insects laying their eggs upon asphalt or glass because these reflect polarized light in the same manner as the water surface and jewel beetles copulating with discarded beer bottles because the surface of the bottles resembles that of females (Robertson et al. 2013).

Maladaptive behaviors in altered environments can cause the decline of populations. In the worst case scenario, this can result in their eventual extinction of the population and perhaps even of the species. A population decline is especially likely when the environmental change is rapid and there is not enough time for evolutionary adaptation. For instance, juvenile African penguins (*Spheniscus demersus*) use cold surface water with high chlorophyll levels as a cue of high fish abundance. However, overfishing by humans has drastically decreased fish stocks in areas where these conditions apply, while climate change has caused remaining fish to move southward. This has resulted in the penguins now selecting feeding areas where forage fish are scarce. They are thus caught in an ecological trap, which is decimating the population (Sherley et al. 2017).

Species that are especially likely to show maladaptive behaviors in changing environments are species from habitats that have been highly stable in the past. These species are usually less plastic and less able to phenotypically adjust to altered conditions. This is because plasticity has not been needed in the past environment and, hence, has not evolved. Similarly, species that encounter novel conditions, which they have not encountered in their recent evolutionary past, may lack reaction norms that are adaptive under the altered conditions. Genetic adaptation and the evolution of behaviors suited to altered conditions are in turn less likely in species with longer generation time, as these may evolve too slowly to keep track with the changes. Small populations may again lack the genetic variation needed to genetically adapt to changing environments.

## Plasticity of Behavior

The degree of behavioral plasticity that an individual expresses depends on its reaction norms for the behaviors, as well as on how these norms have been molded by environmental factors, parental effects, and learning during the life span (Tuomainen and Candolin 2011). Thus, both

genes and experiences during development influence behavioral responses and their plasticity.

Behavioral responses to environmental change can largely be divided into three different forms: (1) The behavioral response may be more or less fixed so that an animal always responds in a particular way to the stimuli, such as attacking a prey when detecting it. (2) The behavioral response may be plastic, and the animal adjusts its behavior to the exact nature of the stimuli, according to its reaction norm. For instance, a predator may adjust its attack behavior to the size or escape ability of the prey. (3) The behavioral response may change during the life span, depending on the conditions that the individual encounters during its lifetime, as well as on its ability to learn new behaviors or improve its skills. For instance, a predator may acquire more advanced hunting skills with age and, hence, attempt to catch prey it would not have aimed at when younger and more inexperienced.

The degree and form of behavioral plasticity are generally adaptive in the natural, undisturbed environment, within the constraints that arise because of other traits (discussed in more detail later). This is because selection across generations has promoted the evolution of behavioral plasticity that maximizes fitness in a particular habitat or context.

## Early Life Experience and Development

Experiences during early development can have persistent effects on behavior into adulthood, through parental effects as well as through direct effects of the environment on the developing individuals. Parental effects arise when the conditions that the parents encounter during their lifetime affect the offspring. This can be through the quality of parental care; the transfer of hormones and nutrients via egg yolk, placenta, and milk; or through transgenerational epigenetic effects that alter the expression of the genes encoding for behavior. Parental effects usually improve offspring fitness and are adaptive. This is because improved offspring fitness increases also the fitness of the parent, which selects for beneficial parental effects. For instance, breeding western bluebirds (*Sialia mexicana*) influence the

aggression and dispersal behavior of their offspring by biasing the birth order of the offspring by sex. When population density increases and the availability of resources declines, females produce more aggressive, dispersive sons. These disperse and colonize new areas where competition for resources is lower and conditions are more favorable (Duckworth et al. 2015).

The conditions that the offspring encounter during development can similarly influence behaviors expressed in later life (Sachser et al. 2013). For example, western black widow spiders (*Latrodectus hesperus*) experiencing poor food conditions during development mature at a smaller size and are more aggressive than well-fed spiders (DiRienzo and Montiglio 2016). These small, aggressive spiders build webs that differ in structure from those of well-fed spider; they are lighter and more efficient in catching prey but less safe. The lower safety implies that poor condition spiders take higher risks in favor of larger food intake. This is probably an adaptive adjustment as the impact of foraging on fitness increases with deteriorating body condition, while the investment into avoiding predators may not improve fitness when body condition endangers survival. Interestingly, if the body condition of the spiders improves in later life, the spiders start building denser and safer webs. However, the webs are still less safe than those of spiders well-fed during development, which indicates that the web-building behavior cannot be fully adjusted to changes in body condition later in life – some degree of maladaptation may still occur.

The influence of environmental conditions on behaviors is often mediated by effects on the development of morphological and physiological characteristics, such as body size or the functioning of the endocrine system. Poor environmental conditions usually result in a small body size, which in turn can impinge on behaviors such as aggression and reproductive behavior. For instance, the larvae diet of dung beetles determines their body size and horn size as adults and, hence, their reproductive tactic. Well-fed males of *Onthophagus acuminatus* develop large horns that they use in the fight for females. Small males, on the other hand, who have experienced

poorer food conditions, develop tiny horns, or no horns at all, and attempt to steal fertilizations by sneaking on pairs of mating beetles (Emlen 1994).

The timing of maturity can influence the mating tactic adopted, as it determines the size of the individual during reproduction. In the coho salmon (*Oncorhynchus kisutch*), males that mature precociously at a small size become “jacks” that sneak on the spawning grounds, while males that mature at an older age when larger become “hooknoses” that fight for females (Gross 1985). A further possibility is that the behavioral tactic adopted changes over the life span of the individual as it grows. In the Azorean rock-pool blenny (*Parablennius parvicornis*), males adopt a sneaking or satellite tactic when small and switch to a nesting, courting tactic when larger (Oliveira et al. 2001). Satellite males are males that are attached to the territory of a nest-holder and help this in defending the territory in exchange for occasional matings.

The adoption of different reproductive tactics is generally adaptive in the natural environment; it maximizes the fitness of individuals that differ in condition and in prerequisites for various fitness-linked behaviors (Gross 1996). However, if conditions change, the adaptedness of the different tactics may change as well.

### Population Characteristics

The density and structure of the population can influence the behavior of the individuals in the population. The impact may be mediated through competition for resources and mates. For example, elks (*Cervus canadensis manitobensis*) adopt a more generalist habitat selection strategy when population density increases; they choose their preferred habitat – mixed forests – less often when density is high, and their home ranges are smaller (van Beest et al. 2016). These changes are likely to be adaptive, as generalist strategies usually yield the greatest fitness return at high densities, while specialist strategies are more favorable when density is low and the competition for preferred resources is weak. Thus elks appear to be able to adaptively alter their habitat choice in response to changes in population density.

Changes in the operational sex ratio (OSR) – the ratio of fertilizable females to sexually active males – can alter the intensity of competition for mates and, hence, mating behavior. For example, male guppies (*Poecilia reticulata*) decrease their courtship activity when the OSR becomes more male biased and fewer females are available to mate with. Instead males start interfering with the courtship behavior of other males, with the aim to disrupt their mating attempts and, in so doing, make the females available as mates. This may increase the mating success of dominant males in relation to subdominant males. Female guppies, in turn, are more selective when more males are available to choose among; they show a stronger preference for colorful males, as the color generally indicates male quality (Jirotkul 1999). Thus, changes in the OSR in guppy populations influence both male-male competition and female choice.

Changes in population size or structure can influence the degree to which individuals help and support each other and, hence, their social behavior. Change in relatedness (kinship) among individuals is particularly likely to influence cooperation. This is because individuals are expected to favor close relatives to gain inclusive fitness benefits; helping relatives with shared genes to reproduce can increase the number of copies of their own genes (or alleles) that are passed on to the next generations. Cooperation is therefore most beneficial among related individuals. If the degree of kinship changes, cooperative behaviors may change as well. For instance, flocks of long-tailed tits (*Aegithalos caudatus*) show more helping behavior during breeding when the flock contains closer related individuals (Napper and Hatchwell 2016).

## Learning

The ability of animals to learn new behaviors, or modify existing ones, can increase the adaptive value of their behavioral repertoire. Learning occurs as a result of an individual's experience and practice. The ability varies among species as well as within species, depending on genetically determined capacities, as well as on environmental and parental effects. Learning requires that the

individual can perceive its behaviors and change them. The changes may occur through habituation to the conditions, such as the presence of humans that pose no predation risk in urban areas or by adopting new behaviors, such as learning to capitalize on the food found in garbage cans.

New behaviors may be adopted through associative learning, such as through trial and error or by imitating other individuals. Young zebra finches (*Taeniopygia guttata*), for instance, learn how to build nests by observing nest building by familiar conspecifics (Guillette et al. 2016). Interestingly, the finches don't learn new skills if observing unfamiliar conspecifics. This indicates that the use of social information depends on familiarity. Such group-dependent learning of new behaviors can promote the cultural transmission of information within a social group.

However, learning is not always adaptive. For instance, the imitation of the behavior of others may not benefit imitators that differ in other characteristics. An individual in poor condition that copies the behavior of an individual in good condition may expend more energy on the behavior than it can afford, or the behavior may expose it to increased risk of predation or attacks from other individuals. Thus, learning is under selection and can evolve as other traits.

## Optimal Behavior: Trade-Offs and Constraints

Trade-offs among behaviors limit plasticity. For example, the need to watch out for predators restricts the rate at which an individual can forage, while the opportunity to mate can reduce vigilance for predators. The optimal balancing of investments among various behaviors depends on their fitness benefits. Because being killed by a predator has a larger impact on fitness than a slight reduction in food intake, animals may forgo foraging opportunities for safety. Similarly, the possibility to reproduce may surpass the benefit of prolonging life by evading predators, particularly in animals with only a few possibilities to mate during their lifetime.

The fitness benefits of behaviors can vary depending on life history stage, body condition, and environmental factors and influence the investment into them. A young animal may invest

in safety rather than in reproduction if more reproductive opportunities are available at an older age when larger and more experienced. An old individual, on the other hand, that nears the end of its life span and, hence, has few future reproductive opportunities, may invest in current reproduction rather than in safety and in extending its life span. For example, male threespine stickleback (*Gasterosteus aculeatus*) takes larger risks toward the end of their single breeding season: they are more likely to engage in conspicuous reproductive activities in the presence of predators and develop more bright nuptial coloration that attracts predators as well as females (Candolin 1998, 2000).

Changes in environmental conditions that alter the costs and benefits of behaviors can similarly influence the investment into them. For example, the hunting of top predators that reduces their abundance decreases predation risk for smaller species. These may then spend less time watching out for predators and instead increase their foraging rate. Such behavioral adjustments are usually adaptive and improve fitness. However, adjustments can be maladaptive when novel environmental conditions are encountered and the behaviors have not been shaped by evolution to suit these. The adaptedness of behavioral adjustments depends on the ability of the animal to perceive the changes as well as to respond adaptively to these. Species may fail to perceive the changes, or they may lack reaction norms for responding adaptively to these. For instance, many species reduce their normal activities when encountering humans, although the humans pose no risk (Frid and Dill 2002). For instance, birds are less likely to establish breeding territories and reproduce in forests where they are disturbed by walking humans (Botsch et al. 2017).

Various constraints may further limit the degree to which behaviors are expressed. For instance, an animal may not be able to increase its foraging rate because of its hunting tactic, long handling time, or slow metabolism. For instance, butterflies that feed on nectar from deep-tubed flowers cannot increase their suction time by developing longer proboscides (elongated mouthparts). This is because the length is constrained by

manipulation times per flower; the longer the proboscis, the more time the butterfly has to spend handling the flower, and this functional cost limits elongation and nectar intake (Bauder et al. 2015). In addition, the perpetual coevolution between interacting species can prevent behaviors from reaching maximal optimality. For instance, predators continually evolve traits that make it more difficult for prey to detect them, while prey evolve counteradaptations that improve their ability to detect the predators, such as improved hearing or smelling. This eternal coevolution may result in neither species behaving completely optimally at any time.

Because of various trade-offs and constraints, most behaviors are not maximally expressed or expressed in the most profitable way. They are instead expected to evolve toward an optimal state under prevailing conditions, considering the various constraints and the trade-offs that limit their expression. Foraging rate, for example, is a compromise among hunger level, body condition, the necessity to avoid predators, and the constraints imposed by morphological and physiological characteristics. Changes in environmental conditions that disrupt the behaviors from their optimal state may require the animals to adjust their behaviors accordingly to maintain their high fitness. If plastic adjustments are not possible, because of various constraints and the lack of adaptive reaction norms, selection for evolutionary alterations in behaviors will strengthen. In the following section, I will discuss the likelihood that animals can evolve better adapted behaviors when phenotypic plasticity is not enough.

## Evolution of Behavior

The evolution of behavior depends on the strength of selection and on the existence of genetic variation in the direction of selection, as well as on the influence of epigenetic effects on the expression of genetic variation. When the environmental change is gradual, as is usually the case during natural changes, animals may gradually adapt their behavior to the new conditions. The evolution may occur through beneficial mutations

spreading in the population, i.e., through selective sweeps, as well as through immigrants bringing new genetic material into the population, i.e., through gene flow. Moreover, hybridization between species can incorporate new genetic material into their gene pools. Such gradual changes are usually adaptive, with natural selection favoring genes and alleles that improve the fitness of individuals. Increased fitness of individual may in turn increase the viability of the population.

Behaviors can change also through random evolutionary changes – genetic drift – particularly in small populations or when a new population is founded by only a few individuals with limited genetic variation (founder effect). Thus, the split of a population into smaller subpopulations because of habitat fragmentation can result in the subpopulations evolving in random directions. For instance, the small and relict population of brown bears in the Italian Apennine Mountains differs in aggressiveness from other bear populations because of random genetic drift. It became separated from other populations by farming and forest burning in Neolithic times and developed reduced aggressiveness through high inbreeding and random fixation of alleles (Benazzo et al. 2017). Such random changes may not necessarily be adaptive. However, populations with maladaptive behaviors are expected to be quickly wiped out. In the case of the Apennine brown bear, the population has survived despite reduced aggressiveness, as the number of competitors has decreased and also because the less aggressive temperament allows coexistence with humans.

When only a few individuals survive to a change in environmental conditions, a population bottleneck occurs that can drastically decrease the amount of genetic variation in behavior. The bottleneck can either increase or decrease the fitness of the population, depending on the stability of the environment after the bottleneck. Bottlenecks can increase population viability by selecting individuals best adapted to current conditions, as only the best fit individuals, with behaviors well suited to the conditions, are expected to survive. On the other hand, bottlenecks can decrease population viability by impeding adaptation to further

changes in the environment, as genetic variation is lost.

In general, the ability of a population to evolve behaviors better suited to altered environmental conditions depends on the rapidity of the change in relation to the generation time of the individuals and on population size and the magnitude and direction of genetic variation. Species with longer generation time, typical for larger top predators, are less likely to adapt their behavior to rapid environmental changes. Small populations, or populations that have not encountered similar conditions in the past, may again lack the genetic variation needed to adapt. In addition, mutations may be too slow to arise to rescue small populations, and immigration of individuals with beneficial alleles may be unlikely if rarer species. When populations are not able to adapt by evolving behaviors better suited to altered conditions, the populations may decline and eventually go extinct (Reed 1999).

When the requirements for evolution are fulfilled, in terms of suitable genetic variation and ample time for evolutionary changes, evolution may still not occur because of various constraints. Trade-offs among traits are particularly common causes of restricted evolution. For instance, a population that has the genetic variation needed to evolve a foraging tactic that reduces predation risk may not evolve the tactic because it would have negative effects on foraging rate. Similarly, various morphological and physiological constraints may limit evolution, such as the evolution of faster escape speed, as this is limited by physiological, energetic, and biomechanical factors. Thus, the evolution of behaviors is constrained by correlations with other traits and by various genotypic and phenotypic limitations.

## Interaction Between Plasticity and Evolution

Phenotypic plasticity – the ability of an individual to alter its characteristics in response to changes in the environment – can influence the evolution of behaviors, by either facilitating or constraining evolutionary changes. Plasticity in behavior can

facilitate evolution by promoting the persistence of a population in a changing environment, as this allows more time for selection to act on heritable variation. Plasticity can also reveal hidden genetic variation that selection can act on and thereby also facilitate evolution. Alternatively, plasticity can constrain evolution by hiding genetic variation.

Whether plasticity reveals or hides genetic variation depends on how it influences the distribution of phenotypes in relation to genotypes in the population. If plasticity results in different genotypes producing the same phenotype, this hides genetic variation, which constrains evolution. On the other hand, if plasticity increases phenotypic differences among genotypes (while maintaining the correlation between phenotype and genotype), this improves the detectability of genetic variation, which can facilitate evolution. An example of behavioral plasticity constraining evolution by hiding genetic variation is the response of the reef fish *Acanthochromis polyacanthus* to elevated CO<sub>2</sub> levels. Chronic exposure of juveniles to high CO<sub>2</sub> reduces their variation in behavioral response to chemical alarm cues of predators (Welch and Munday 2017). This masks genetic variation in antipredator behavior, which reduces its heritability. Reduced heritability decreases in turn the potential of the species to genetically adapt to elevated CO<sub>2</sub> levels. Because the plastic responses are maladaptive – the fish become less responsive to chemical alarm cues – the species may not be able to adaptively adjust to rising CO<sub>2</sub> levels in the ocean, neither through plasticity nor through evolutionary changes.

Behavioral plasticity can influence evolution also by moving the phenotypes in the same or opposite direction to selection, depending on whether plasticity is adaptive or maladaptive. If the phenotypes are moved in the same direction as selection (adaptive plasticity), so that the phenotypes come closer to the optimum phenotype, selection will relax, which constrains evolution. If plasticity is maladaptive and moves the phenotypes further from the optimum, in the opposite direction to selection, selection will strengthen, which can promote evolution. However, whether maladaptive plasticity promotes evolution

depends also on its effects on genetic variation. In the above example with reef fishes responding to elevated CO<sub>2</sub> levels, the maladaptive plastic responses hide genetic variation, which constrains evolution.

Phenotypic plasticity can be lost over evolutionary time through genetic accommodation or assimilation. The phenotype originally produced through plasticity then becomes genetically encoded via natural selection. It is then fixed and can no longer change with environmental conditions. For instance, the production of alternative, diet-induced, larval ecomorphs of spadefoot toads is replaced by the production of only one ecomorph when several species compete for food. When the species occur separately, in allopatry, they produce two ecomorphs: omnivores that eat detritus and carnivores that specialize on shrimp and other tadpoles. When two species are brought together and occur in sympatry and, hence, have to compete for detritus, one of the species loses the plasticity and becomes nearly fixed for producing carnivores only. The loss of plasticity occurs through genetic accommodations, whereby the ecomorph becomes genetically canalized. The loss of plasticity is caused by changes in the regulation of gene expression (Levis et al. 2017).

## Variation Among Individuals

Within a population, there is often large variation among individuals in their behavior. This within-species variation can be adaptive and improve individual fitness or, alternatively, be maladaptive if some individuals are not able to behave adaptively because of various constraints or past experiences or evolutionary processes (the ghost of selection past). The variation in behavior can be genetically determined or the results of phenotypic plasticity or a combination. Most often the variation is a combination of the two, with environmental conditions and intrinsic properties of individuals modifying genetically determined behavioral reaction norms. For instance, during invasions into new areas, individuals at expanding

range edges often differ in their behavior from individuals in the range core: they are often bolder and more exploratory and aggressive. These differences in behavior can have a genetic basis but also be modified by experience. For example, cane toads (*Rhinella marina*) at invasion fronts are bolder and take more risks than toads in range cores. These individual differences have a genetic basis but can be modified by individual experiences of environmental and demographic conditions (Gruber et al. 2017).

Within-population variation in social and reproductive behaviors is often adaptive and promoted by selection. For instance, individual great tits (*Parus major*) follow alternative social strategies depending on their behavioral characteristics. Proactive great tits – which are fast-exploring individuals – form weak associations with a great number of conspecifics and move between foraging flocks, while reactive tits, which are slow-exploring birds, form stronger and more stable relationships with a few conspecifics (Aplin et al. 2013). These social strategies are adaptive and maximize individual fitness as well as the social organization of the population.

Adaptive, alternative reproductive behaviors are common in species where individuals attempt to monopolize mates. Individuals in poor condition, who are not able to acquire mates through the dominant tactic, such as by establishing a territory and courting females, may adopt an alternative mating tactic, such as sneaking. The alternative behavior is then a conditional strategy that improves the fitness of the individual compared to attempting to reproduce through the dominant strategy. Alternative reproductive behaviors can be also genetically determined and have equal fitness that is maintained through frequency-dependent selection. In the lek-breeding ruff (*Philomachus pugnax*), three genetically determined reproductive tactics occur: territorial “independent” males with dark plumage that defend courts on leks, white satellite males that join the territorial males on courts and compete for matings by co-displaying to attract females, and small, female-mimicking faeders that visit the courts of territorial males and attempt rapid

copulations when females solicit matings from displaying males (Jukema and Piersma 2006).

Maladaptive behaviors are especially common when individuals are not adapted to prevailing environmental conditions. In particular, when conditions are changing rapidly because of human activities, some individuals may behave maladaptively because their reaction norms are not suited to the novel conditions. Such individuals will eventually be wiped out from the population. However, if the environment continues to change, the population may never be composed of mostly well-adapted individuals and, hence, never become well adapted to local conditions.

## Conclusion

The behavior that an animal expresses in different situations is a major determinant of its fitness. It influences foraging success, predator avoidance, social interactions, dispersal, and reproductive success. Behaviors are determined by genetically determined reaction norms, which can be influenced by environmental factors, early life experiences, and learning. Behaviors are usually more or less adaptive in the natural environment. However, sudden environmental changes, particularly those induced by human activities, can seriously disrupt their adaptive value. Because behavioral responses are usually the first response to altered environmental conditions, they can have a decisive impact on the success of populations in disturbed environments.

The influence that behavioral responses have on populations in changing environments is an emerging research field. Considering the rate at which humans are altering environments and the fact that biodiversity is seriously declining in many areas of the world, more information is needed on the factors that influence population viability in disturbed environments. Important topics in need of more attention are the degree to which behaviors contribute to the decline or growth of populations and how behaviors can be considered in conservation and management practices to improve population viability.

## Definition

A memory advantage for information processed in a fitness-relevant domain (e.g., animacy, mortality salience, mate selection)

## Introduction

The adaptive memory literature describes a memory benefit for information processed for its fitness value. Early iterations of this finding, first reported by Nairne, Thompson, and Pandeirada (2007), showed participants' incidental recall was greatest after they had rated a set of words according to how well they would assist them “find[ing] steady supplies of food and water and protect[ing themselves] from predators” (p. 264). This “survival advantage” has been widely replicated across various laboratories, research designs, tasks, stimuli, languages, age groups, and other manipulations and factors (Kazanas and Altarriba 2015; Schwartz et al. 2014). Following these replications and extended research, Nairne and Pandeirada (2016) proposed a functionalist explanation: a general survival optimization system flexible enough to account for the now, far-reaching literature. They described an ultimate mechanism for this effect, with a highly flexible system of resources humans use to detect and respond to threats and related cues from the environment. This flexibility can account for survival processing advantages observed for scenarios describing various environments, eras, predators, and more. Recently, researchers have begun to explore whether these memory advantages extend to other fitness-relevant domains – described as the field of “adaptive memory” – such as those pertaining to animacy and mortality salience (Altarriba and Kazanas 2019). Additional domains, including contamination, cheater detection, and mate selection, have also been explored for their mnemonic value. Findings from these various domains show some are more strongly linked to memory than others, perhaps the result of more focused attention, increased arousal, and

so on. The noted discrepancies across domains suggest some differences in the processes and mechanisms involved in these tasks, though each reflect the selection pressures theorized to have shaped human evolution, including its cognitive development.

## Animacy

One of these domains of research investigates the relationship between animacy and memory. VanArsdall, Nairne, Pandeirada, and Blunt (2013) tested memory for nonwords presented with either a living property (*dislikes tomatoes*) or a nonliving property (*requiring a key*). Both recognition (Experiment 1) and recall (Experiment 2) were higher for nonwords presented with living properties. Similar designs with children as young as 4 years old show similar results (Aslan and John 2016), suggesting some innate prioritization of living things.

Nairne, VanArsdall, Pandeirada, Cogdill, and LeBreton (2013) then reexamined results originally presented by Rubin and Friendly (1986), asking what lexical characteristics best contribute to memory. Rubin and Friendly had originally reported the significance of imagery, availability, and emotionality, though they had not considered recall attributed to animacy. Nairne et al. (2013) collected new ratings showing animacy may be the strongest predictor of recall. For example, the positive correlation between animacy ratings and recall was twice that of imagery. Next, they tested intentional learning for animate and inanimate words, matching the two word types on nearly a dozen lexical variables. Recall was again higher for the animate words, extending the earlier findings they had reported with nonwords (VanArsdall et al. 2013).

Additional support for this animacy advantage comes from a series of experiments conducted by Bonin, Gelin, and Bugaiska (2014). In their first two experiments, participants categorized words (Experiment 1) or pictures (Experiment 2) as either animate or inanimate. In both experiments, their participants categorized animate stimuli faster than inanimate stimuli. In addition, recall

was higher for animate stimuli. Experiment 3 included a remember-know recognition task, with participants indicating whether they remembered, knew, or guessed when responding. Overall, animate words were recognized faster, with participants also more confident they remembered the animate words. Their final experiment tested whether semantic richness factors into animacy effects. Although the words had been originally matched on imagery ratings, Bonin et al. collected a new set of independent ratings pertaining to sensory experience (e.g., taste, touch, sight). These ratings were equivalent for animate and inanimate words, reducing the likelihood differences in memory are a function of sensory experiences.

Bonin, Gelin, Laroche, Méot, and Bugaiska (2015) investigated additional explanations for these animacy effects, including the role of richness/elaborative encoding and interactive imagery. Two of their experiments showed greater recall with animate words, despite a cognitively demanding categorization task during encoding. The authors replicated the animacy effect again, even with a dual-task procedure. These results suggest animacy advantages are largely independent of cognitive resources, such as attention, and they do not rely on richness or elaborative encoding, unlike the survival advantage (Kroneisen et al. 2013). In one additional experiment, Bonin et al. (2015) asked participants to create interactive situations for animate and inanimate words. Animate words were again more memorable, though the interactive imagery task did not add to this effect. Leding (2018) explored a related hypothesis, testing whether deeper processing underlies animacy effects. In one experiment, participants processed animate and inanimate words either shallowly (*whether each word contained an "e"*) or deeply (*according to its pleasantness*). In both conditions, participants recalled significantly more animate words than inanimate words, reducing the likelihood deeper processing promotes these animacy effects. Perhaps participants do not need any explicit tasks or encoding instructions to attend to animacy.

Recently, Meinhardt, Bell, Buchner, and Röer (2020) have argued otherwise, citing evidence

richness of encoding could be a proximate mechanism of these animacy effects. In their experiments, they showed memory advantages for animate words were mediated by participants' generated ideas for those animate words. Experiments with Nairne et al.'s (2013) word list, along with additional experiments using a new word list, resulted in similar findings: Participants generated a greater number of ideas for animate words than for inanimate words; this was followed by their recalling a significantly greater proportion of animate words. These findings encourage additional research, exploring whether this richness arises automatically or whether it drains cognitive resources, as would be the case with sustained attention (though they note it is not likely due to mental arousal, Meinhardt et al. 2018).

Threat or *perceived threat* appears to be unrelated to these memory advantages. Across a series of experiments, Leding (2019a, b) has shown animacy effects persist even after factoring in the role of threat. After norming a new set of words to compare animacy and threat effects separately, she tested recall of the combined word types: animate (both threatening and nonthreatening) and inanimate (both threatening and nonthreatening). Independent main effects of both animacy and threat – without a significant interaction – strongly suggest threat does not contribute to the animacy effect (see also Leding 2020). Importantly, these findings replicated under both intentional learning and divided attention conditions (Leding 2019a) and with online data collection (Leding 2019b). Findings from the divided attention condition support previous work showing the automaticity of these effects, as animacy processing cannot be too demanding of a task if it persists under these complex conditions (e.g., Bonin et al. 2015).

Gelin and colleagues have examined the generalizability of animacy effects to various encoding instructions (Gelin et al. 2017) and types of contextual information (Gelin et al. 2018). They replicated the animacy effect across scenarios including Nairne et al.'s (2007) survival and moving scenarios, a novel tour guide scenario, and a pleasantness-rating task. These results show reliable recall advantages across four

scenarios and their encoding instructions. Additional experiments found animacy advantages for a word's spatial information (its location on a computer screen) and temporal information (its presentation at the beginning, middle, or end of a list). These results highlight the generalizability of animate word memory to other aspects of the study design.

One set of studies has provided some counter-intuitive results for the animacy literature. Studies with cued recall tasks are not as consistently in favor of animacy advantages, with some even showing *reverse animacy effects*. VanArsdall, Nairne, Pandeirada, and Cogdill (2015) used animate and inanimate Swahili-English word pairs to test animacy effects in paired-associate learning (i.e., learning a second language). Memory for both animals and people was greater than memory for furniture and general objects. Meanwhile, Popp and Serra (2016) found a reverse animacy effect with their word pairs, as their results showed better memory for object-object word pairs, relative to animal-animal word pairs. They replicated this finding in a second experiment, with additional results showing null effects between Swahili-English and English-Swahili animal- and object-based word pairs. Finally, in their last experiment, recall was higher for object-object word pairs than for animal-animal word pairs, as well as for mixed word pair types (animal-object and object-animal). Popp and Serra's (2016) results suggest attentional capture underlies these results with cued recall, as participants' attention is drawn to processing the individual animate words from each pair, rather than encoding both words from the word pair. Notably, a similar argument for attentional capture has been made for other tasks, with Leding (2020) finding lower discriminability for both animate and threatening items during recognition.

Kazanas, Altarriba, and O'Brien (2020) continued this line of research, testing animacy with cued recall following survival, moving, and pleasantness-rating encoding instructions. All participants learned a set of English-Spanish animate and inanimate word pairs. Word pairs were presented visually and auditorily, paired with a black and white image, and were then tested

with sentence-completion, picture-naming, and matching tasks. The authors found reliable reverse animacy effects across all conditions and tasks: In each one, participants' memory for inanimate word pairs was significantly greater than their memory for animate word pairs. Findings across free and cued recall do appear to differ, with researchers surmising the animate word of each word pair pulls attention from the other word, preventing successful paired-associate learning. This is likely to be an automatic feature of animate word processing, as animacy effects tend to replicate in designs with cognitively demanding features and additional tasks (e.g., Bonin et al. 2015; Leding 2018). Thus, future work is needed to better understand the proximate mechanisms underlying the animacy effect, as they do not appear to be elaborative encoding (Bonin et al. 2015) or mental arousal (Popp and Serra 2018), nor can they be attributed to semantic richness (Bonin et al. 2014).

## Mortality Salience

In another aspect of adaptive memory, the mortality salience literature tests whether the notion of death underlies memory advantages like those found following survival processing. Death processing, or mortality salience, involves thinking about one's own death, the circumstances that might bring about death, and the afterlife. Differing from the animacy literature, these findings are a bit more variable, with some finding mortality salience – and the memory benefit from information processed for its mortality salience – could share some of the mechanisms underlying the survival advantage or rely on another set of mechanisms entirely (Hart and Burns 2012).

The “predator” described in Nairne et al.'s (2007) survival scenario represents one of the elements that may heighten a participant's sense of mortality. Soderstrom and McCabe (2011) investigated scenario eras (comparing ancestral and modern survival processing), as well as various predators, for their effect on the survival advantage. They included five conditions in their

study: the standard survival scenario (Nairne et al. 2007), a survival scenario with a zombie predator, a modern (city) survival scenario with attackers, a modern (city) survival scenario with zombies, and a pleasantness-rating control condition. In what was initially described as a controversial finding, recall with the zombie predator scenarios was greater than recall with the predator and attacker scenarios, across both ancestral and modern scenarios. These findings challenged the idea that ancestral priorities underlie the survival advantage, given the low likelihood of encountering a supernatural predator. Similarly, using a demon predator – replacing *predator* with *demon* in the survival scenario – Kazanas and Altarriba (2017) showed participants recalled more words than the standard predator version of the scenario. Wanting to examine the predator's function in enhancing memory, they tested whether more dominant predators, such as a demon, could produce larger memory advantages. Predators were pilot-tested, with demons rated significantly more negative than zombies and other creatures, though they still possess traits consistent with actual, living predators. Despite these differences, the magnitude of the survival advantage, relative to pleasantness ratings, was equivalent across the demon and predator scenarios.

However, these seemingly controversial findings may actually support the general survival optimization system proposed by Nairne and Pandeirada (2016). Zombies and demons could represent *super predators* that activate self-preservation mechanisms and boost recall (Nairne 2014). Presenting a survival scenario describing a super predator may activate a stronger, more automatic response, lending itself to the most focused attention and encoding for later retrieval (Kazanas and Altarriba 2018).

Hart and Burns (2012) considered whether the results described by Soderstrom and McCabe (2011) might be a function of mortality salience, meaning the complexity we attribute to death could motivate various cognitive processes. Thus, considering one's own death will enhance encoding and long-term retention. Hart and Burns (2012) and Burns, Hart, and Kramer (2014a) have investigated this “dying to remember” hypothesis

(Burns and Hart 2014) with a series of related experiments.

In one of these experiments, Hart and Burns (2012) assessed recall following a priming phase, instead of the typical word rating task. Participants were asked to describe their emotions as they considered either their own death or watching television. They also completed the Positive and Negative Affect Schedule (PANAS; Watson et al. 1988), to assess the impact of various mood states on performance. Finally, participants rated a list of words on their pleasantness. Recall for these words was greater following the mortality salience prime than the television prime. Importantly, recall was not mediated by either the PANAS score or pleasantness ratings for the list of words, suggesting a mortality salience effect not influenced by these factors.

Later, Burns et al. (2014a) asked whether there is a functional connection between the survival advantage and the mortality salience effect. The authors created mortality salience and survival scenarios emphasizing participants' need to prepare emotionally, mentally, and physically for their death or survival. The authors found similar recall rates across the survival and mortality salience conditions (both significantly greater than pleasantness ratings), replicating this pattern across three experiments, even after refining the mortality salience scenario to better match the survival scenario, and using a larger, online sample and a new set of words. To test whether self-referential processing was responsible for this memory advantage over pleasantness ratings, they replaced the pleasantness control condition with the television-watching scenario used by Hart and Burns (2012). Recall was again significantly greater in the survival and mortality salience conditions, relative to the control condition. These findings suggest the advantage cannot be attributed to self-reference alone. Additionally, with similar recall rates following these manipulations, they reduced the likelihood these conditions rely on different mechanisms (see also Zhao et al. 2018). In fact, Burns, Hart, Kramer, and Burns (2014b) argue mortality salience and survival advantages both rely on item-specific processing, with some of their recall data indicating

they also rely on relational processing. Their mechanisms may not only overlap, but they also may activate the same cognitive processes.

Other work has suggested different mechanisms underlie survival and mortality salience advantages (Bell et al. 2013; Klein 2012), finding differences in the magnitude of memory advantages across survival and mortality salience processing. In one example, Klein (2012) created similarly worded conditions but found recall from the mortality salience condition did not differ from the pleasantness-rating condition and these recall rates were significantly *lower* than survival processing. Ratings collected from participants indicated they generated significantly more thoughts of planning while engaging in survival processing, relative to mortality processing, suggesting some role of planning in the survival advantage, but not in mortality salience effects. Considering these differences, Klein (2012) concluded survival and death relevance may actually rely on different mental processes and cognitive activities.

Research into mortality salience has been mixed, with some studies finding lower recall rates than survival processing (Bell et al. 2013; Klein 2012) and others finding similar recall between the two scenarios (Burns et al. 2014b). These mixed findings lead researchers to question whether these scenarios promote and rely on different cognitive mechanisms. As some others suggest survival and death processing do not completely overlap, future research should determine the proximate mechanisms they share, as well as those defining them. Future research will also benefit from a new set of normative data, constructed by Alonso, Díez, and Fernandez (2021). Their norms include 750 Spanish concrete nouns, all rated for their relevance to situations described as "avoiding death by protecting from predators and other kinds of harm" (p. 157). Researchers will find these useful when wanting to control for these dimensions; perhaps they might also test for differences in language acquisition, such as advantages in acquiring words pertaining to one's mortality, or specific biases and attention on one's mortality, related to various psychopathology.

## Contamination

Adaptive memory may also extend to scenarios involving contamination, with researchers testing hypotheses grounded in the human Behavioral Immune System (BIS; Schaller 2006): a system coordinating detect-and-avoid processes, such as those protecting humans from various contaminants, pathogens, and more. Previous work has demonstrated meaningful memory advantages for this notion of “contamination processing.” For example, Chapman, Johannes, Poppenk, Moscovitch, and Anderson (2013) showed participants disgusting, fearful, and neutral images, either concurrently with a line-discrimination task or alone. The participants then completed a remember-know recognition task, following a delay of either 10 min, 45 min, or 1 week. Advantages in memory for the disgusting images were observed after just 10 min; these advantages increased over time, with better recognition performance at the longer retention intervals. This was the case across all participants, including those multitasking with the line-discrimination task. Disgusting imagery also slowed reaction time, suggesting these advantages may be the result of disgust narrowing participants’ attention (see also Bell and Buchner 2010). Important to this discussion, disgust appeared to be a more motivating force than did fear, with the researchers wondering if emphasizing specific subcategories of disgust (e.g., food, injuries) might further increase these effects.

Fernandes, Pandeirada, Soares, and Nairne (2017) tested whether the Behavioral Immune System also extends to memory for contaminated items. Their participants read scenarios describing how items had been touched by either sick or healthy individuals. Items were paired with verbal descriptions (e.g., a person with a constant cough) and faces with varying physical appearances. Across these manipulations, participants remembered more items when they had initially appeared with descriptions or faces suggesting a sick person had touched them. They also observed better source memory for those items. Importantly, this effect disappeared when participants were told the actors had applied makeup merely to *appear* sick.

Thus, an imminent threat would engage true survival processing, as their appearance alone did not motivate some disgust or fear mechanism.

Gretz and Huff (2019) noted similar advantages in source memory and item recognition. Their participants viewed videos showing items touched by individuals described as contagious (a person diagnosed with influenza, sneezing in the video), noncontagious (a person diagnosed with cancer), or healthy. Their results showed a specific contamination advantage, with greater memory for those items touched by the contagious individuals. This was particularly the case for those scoring high on the “germ aversion” subscale of the Perceived Vulnerability to Disease scale (PVD; Duncan et al. 2009), suggesting an applied individual differences variable. Gretz and Huff recommend additional research determining the underlying mechanisms of this effect, as they note the specificity of their findings – that touching an item is not enough to engage Behavioral Immune System mechanisms – to items touched by contagious individuals, *only*.

Critically, contamination processing does not always promote memory advantages. One such example was described by Bonin, Thiebaut, Prokop, and Méot (2019a), who also investigated disgust and fear mechanisms for the contamination effect. One of their experiments asked participants to engage in survival processing when the predator was described as a zombie: either disgusting in appearance or presented as an attacker. Recall following survival processing was equivalent across these two scenarios, though both produced superior recall to a pleasantness control condition. These findings suggest previous results by Soderstrom and McCabe (2011), also involving scenarios describing a zombie predator, were not motivated by disgust. These results also suggest contamination, by way of disgust, is not as effective of a mnemonic as others investigated in the adaptive memory literature.

Contamination does appear to motivate memory in most cases, though, presumably once participants reach some threshold for feeling threatened. Bonin, Thiebaut, Witt, and Méot (2019b) recommend researchers present faces to their participants, with faces providing more

critical cues than scenarios describing touched items. Across their numerous studies, memory advantages involving contamination were limited to those specific cases when they presented faces of infected individuals along with the items they had touched. This effect also extended to source memory for the items, as well as the faces. No memory advantages were observed if these scenarios were merely described to participants, without the presented faces. Thus, the faces were particularly helpful in activating participants' Behavioral Immune System responses.

Contamination studies extend the adaptive memory literature via the Behavioral Immune System. This system is hypothesized to provide the various resources needed to enhance information processing for contaminated items and their sources (e.g., Bonin et al. 2019a; Fernandes et al. 2017; Gretz and Huff 2019). These resources are particularly employed when faces are presented to participants, signaling their poor health (Bonin et al. 2019a), and for the more "germ-averse" participants (Gretz and Huff 2019). Future research will be needed to determine whether memory advantages for contamination are a function of disgust or fear (or perhaps both), as these results remain mixed (Bonin et al. 2019b; Chapman et al. 2013).

### Additional Fitness-Relevant Domains

In addition to animacy, mortality salience, and contamination, researchers have tested several other fitness-relevant problems for their mnemonic value, many of which – like contamination – test the memorability of individuals described in scenarios. Early examples of these studies suggested some limitations of the survival advantage, for example, Savine, Scullin, and Roediger (2011) showed memory advantages did not appear to extend to faces, including real or computer-generated faces, or descriptions of those faces (*he is very good at reading maps*), even when the scenarios involved hostile threats. Similarly, Hou and Liu's (2019) participants showed little differences in their memory for faces rated either trustworthy or untrustworthy, though survival

processing generally promoted face memory relative to a non-survival hunting contest.

As a result, researchers began to study more specific domains, rather than test general memory for faces. Cheater detection is one such domain extending the survival processing literature. Buchner, Bell, Mehl, and Musch (2009) assessed source memory for faces, asking whether participants would better remember a face if it was described as trustworthy than if it was described as a cheater. Buchner et al. (2009) randomly combined faces with cheating, neutral, or trustworthy descriptions. Participants had the best memory for faces paired with cheating descriptions, while memory for trustworthy and neutral faces did not differ. In addition, participants later rated the cheaters as less attractive (Experiment 1) and less likeable (Experiments 2–4). This memory advantage also impressively persisted following a 1-week retention interval (Experiment 3). Importantly, Buchner et al. (2009) showed memory for cheaters was not dependent upon the specific nature of the offense or the cheater's social status. Their subsequent work suggests participants' heightened emotional reactions to the described cheating behavior may account for these effects (Bell and Buchner 2011). They further surmised social contract theory explains these findings; ancestral violations of social exchange would have created a significant burden on their small groups. Perhaps, even small cheating offenses – with direct, negative consequences for the victim – would be remembered, and group members would likely limit future interactions with that individual.

Reproduction and individuals' mate value can also drive memory processing. Derringer, Scofield, and Kostic (2017) tested variants of the survival scenario, such as rating adjectives (*happy*; *secretive*) needed to find a mate or detect sexual/emotional infidelity or rating gifts to bring on a romantic date. In some cases, participants' memory supported adaptive memory advantages, with better memory for adjectives helping participants find a mate, relative to evaluating a co-worker. Other comparisons did not significantly differ, for example, participants did not recall more gifts they would bring on a romantic

date, relative to a housewarming party. These mixed results suggest only some of these manipulations tap into fitness-relevant memory benefits.

Mate selection may provide a more fruitful route for further research. Pandeirada, Fernandes, Vasoncelos, and Nairne (2017) asked female participants to assess male faces and descriptions (*is an honest person; is envious*) for their desirability as a long-term mate or co-worker. Somewhat more conclusively than Derringer et al. (2017), they showed better face recognition and source memory following the long-term mate condition, though participants in the long-term co-worker condition recalled more descriptions. They reasoned the faces likely held participants' attention more so than the verbal descriptions, and, it is likely faces are considered more important for mating contexts than working contexts. Results from these related studies suggest some support for mate selection as a fitness-relevant problem with associated memory advantages.

Together, studies from the cheater-detection and mate-selection literatures provide some indication memory advantages extend to other fitness-relevant domains. However, not all issues attributed to fitness/survival carry these benefits. Sandry, Trafimow, Marks, and Rice (2013) conducted a large study comparing memory across participants who engaged in survival processing to those engaged in rating tasks describing incest avoidance, jealousy, status, and more. They replicated the survival advantage, with better memory relative to the pleasantness control condition, but found no significant differences between the remaining conditions and pleasantness ratings. Their mate-selection and cheater-detection scenarios fared similarly, though some of the more recent studies have reported differing results (e.g., Derringer et al. 2017). Sandry et al. suggest participants directly instructed to consider their survival will be the most motivated to encode (and retrieve) the provided materials.

## Conclusions

From a functionalist perspective, survival memory advantages indicate human memory prioritizes the

encoding and retrieval of fitness-relevant information. Researchers recently began to test the mnemonic value of other fitness-relevant domains, such as those pertaining to the more broad "adaptive memory" literature, including animacy, mortality salience, contamination, cheater detection, and mate selection. Each domain has provided promising results, with memory in several cases equating or surpassing that of various control conditions. Importantly, these memory advantages replicate across numerous tasks, including recall and recognition of words and faces, source memory, and more. An important aim for future research will be to discern the various mechanisms explaining these memory advantages, for example, whether they share or differ from those explaining survival memory advantages.

## Definition

Adaptive radiation can be defined as a type of evolutionary process in which organisms show diversification in physical and anatomical structure from their ancestral species for better adaptations to the changing environment (Schluter 2000).

## Introduction

According to Charles Darwin's book *Origin of Species*, various processes have played an important role in the evolution of spectacular biological diversity on Earth. Among all, adaptive radiation has been considered as the most crucial factor for maintaining this diversity. It is comprised of two main features: speciation (formation of new

species driven by certain ecological conditions) and phenotypic adaptation resulting in the emergence of an array of new species showing distinct morphological and physiological characters. This phenomenon was first put forward by Darwin during his voyage to the Galápagos Islands (Grant 1999) and relies on the notion of ecological opportunity that is described as an abundance of evolutionarily accessible resources underutilized by competing taxa (Schluter 2000).

### Ecological Opportunity: A Prerequisite for Adaptive Radiation

Ecological opportunity is a necessary phenomenon for adaptive radiation to occur. Simpson (1953) proposed that ecological opportunity could become accessible for organisms in four ways:

- (i) Appearance of new resources: Ecological opportunity can prompt adaptive radiation if new resources appear in the given area. In other words, evolutionary diversification of a clade may prove beneficial for other species. For example, the evolution of grasses presented an opportunity for the primitive species of horses to exploit and evolve under changing environmental conditions.
- (ii) Geographic colonization: Geographic colonization has undoubtedly accounted for the majority of adaptive radiations on remote islands like the Hawaiian archipelago, Galápagos Islands, Caribbean islands, etc. One of the main reasons behind this is the absence of species competing for the available resources on islands which were otherwise present on the mainland. Furthermore, the absence of predators may also permit the use of habitats which were earlier inaccessible, thereby facilitating adaptive diversification.
- (iii) Mass extinctions: Mass extinction events leading to the removal of complete or large proportions of ecologically dominant species support the hypothesis of ecological opportunity. After such events, surviving species are released from competitive and

predatory pressure, and are left with plenty of resources that pave the path for their evolutionary diversification. For example, many clades of birds and placental mammals showed explosive radiation after cretaceous-paleogene mass extinction of the dinosaurs (Erwin 2015).

- (iv) Key innovations: Key innovations can be basically defined as evolution of novel features or traits that provides the capability for species to take advantage of available resources which they could not utilize previously and thus promotes adaptive radiation (Rabosky 2014). Examples of key innovations include the evolution of adhesive toepads in anoles and geckos, evolution of wings in birds and bats, and the evolution of pharyngeal jaws in labrid fishes. All these cases of key innovations have opened new opportunities for evolutionary radiation within the existing environmental milieu (Stroud and Losos 2016).

### Classical Examples of Adaptive Radiation

**Darwin's finches:** Darwin's finches are members of tanager bird family Thraupidae and represent the most symbolic example of adaptive radiation inhabiting the patchy and diverse landscape of Galápagos Island. To date, approximately 15 species of Darwin's finches have been identified. These species arose from a single ancestor that probably migrated to Galápagos from the mainland of South America 3 billion years ago. All such species differ from each other in several aspects of ecology, morphology, and songs (Grant 1999). One of the major difference occurred in the shape and size of finches' beak which are specialized according to the primary source of nutrition available to them. For example, the largest ground finch (*Geospiza magnirostris*) has developed the thickest beak, which allows it to break open the hardest seeds. Likewise, the smallest ground finch (*Geospiza fuliginosa*) has evolved a smaller beak, which allows it to specialize on small seeds and the medium ground finch (*Geospiza fortis*) has a medium-sized beak, which facilitates consumption of intermediary sized seeds (Weiner 1994).

**Caribbean *Anolis* lizards:** *Anolis* lizards are another fascinating example of adaptive radiation. There are about 400 species of *Anolis* which are widely distributed in the West Indies as well as mainland Central and South America. These *Anolis* lizards provide an insight to determine how adaptive radiation varies in mainland and island condition. Divergence of *Anolis* on mainland has essentially been attributed to the process of speciation and is not adaptive to any substantial extent. However, *Anolis* on the islands like Cuba, Jamaica, and Puerto Rico have evolved in such a convergent way that each species can be grouped in one of six “ecomorphs” named as trunk-ground, trunk-crown, grass-bush, crown-giant, twig, and trunk depending upon the microhabitat they colonize (Irschick et al. 1997).

**African cichlids:** Cichlids fishes of east African great lakes also show adaptive radiation. There are around 2,000 species of cichlids inhabiting different lakes such as Lake Tanganyika, Lake Malawi, and Lake Victoria. Each species has distinct morphology in terms of habitat, diet, sexually selected traits, and perform various ecological roles including those of scavengers, predators, and herbivores, etc. For example, *Lethrinops furcifer* commonly resides in sandy area nearby beaches whereas *Hemitilapia oxyrhynchus* lives in shallow vegetated environment in Lake Malawi (Konings 2016).

**Hawaiian honeycreepers:** Hawaiian honeycreepers belonging to the family Fringillidae have specific beaks which are well adapted according to their dietary requirements. For example, lower mandible of *Hemignathus wilsoni* is short and sharp for scraping tree bark while its upper mandible is long and curvy for searching out insects underneath the wood. However, *Telespiza cantans* has evolved a thick beak for eating tough seeds. Presently, 17 species are known to exist in the Hawaiian Islands (Olson 2004).

## Conclusion

Adaptive radiation is a remarkable and complex route for evolutionary divergence and is governed by several different parameters such as ecological, genetical, developmental, geographical, etc.

When coupled with ecological opportunity, adaptive radiation resulted in the burst of new species from preexisting species through a process known as rapid speciation. Ever since the publication of the Darwin’s work, this process has managed to amaze and motivate ecologists as well as the public. However, the exact mechanism by which radiation takes place under diverse environmental backgrounds and why it varies among different taxa are still an area of active research. In this regard, more information related to genes and genomes along with detailed knowledge of natural selection will enhance our understanding of adaptive diversification.

The study of arithmetical reasoning and numerical understanding has been a topic of interest for cognitive, developmental, and comparative psychologists for many decades. Questions of whether mathematical processes are innate and how they develop has led to many studies on children's numerical capabilities, including studies designed to help outline the relationships between understanding quantities and numbers and the arithmetical transformations that can change those representations. One well-studied aspect of arithmetical competence in children is the process of addition (e.g., Carpenter et al. 1982). Addition is defined as the process or skill of calculating the total of two or more numbers or amounts. At a young age, children have already gained a simple understanding of the concept of

“more” and “less” (Brush 1978), and then they learn to count. But, it is not until they get older that they come to appreciate addition, subtraction, and other operations. Studies with infants have produced mixed findings regarding sensitivity to addition operations (e.g., McCrick and Wynn 2004), suggesting that, at best, infants make imprecise judgments by recognizing that a numerical change must take place when an additive or subtractive operation occurs but with no implication of the magnitude or direction change from that operation (Wakeley et al. 2000). The ability of young children to grasp only basic properties of numerical transformations and contradictory results with infants provides incomplete evidence for the idea of innate numerical proficiency. However, studies with nonhuman animals provide additional evidence of an evolutionary basis for humans' adeptness with numbers and the mathematical reasoning that underlies addition.

For example, in one compelling case, Boysen and Berntson (1989) trained a chimpanzee named Sheba to enumerate sets of items, and then label those sets with an Arabic numeral by pointing to the correct numeral. After learning to do this, Sheba could then move to separate locations, see multiple sets of items, and provide the label for the total number of items, presumably by adding the sets together. However, it was not clear whether Sheba did this by adding two represented sets (e.g., 2 plus 2 equals 4) or by “counting-on” from the first set to the second (e.g., “1, 2” and then “3, 4”). In either case, the results clearly showed that Sheba could combine spatially discontinuous sets and label them accordingly. Other work with chimpanzees presented a “summation” test in which chimpanzees could select between two arrays of food items. In the early versions, there were two sets, each of a differing number of items, and chimpanzees were highly successful in choosing the larger set. Subsequent experiments showed that those chimpanzees could combine pairs of sets in separate locations into two choice sets, and then choose the larger combined amount of food from the choice sets after summing the items in each pair (Rumbaugh et al. 1987). This was true even when the single-largest set of items was not part of the summed set that had more total food in it.

Other research showed that nonhuman primates could sum symbols for quantity such as Arabic numerals. Olthof et al. (1997) presented squirrel monkeys with Arabic numerals to choose from, and they gave the monkeys a number of food rewards equal to the selected numeral. After monkeys became good at that test, they presented pairs of numerals to be combined to determine the greatest amount of food that could be obtained, and the monkeys learned to do this, even when the single largest numeral was part of the pair that was less overall (similar to Rumbaugh et al. 1987). In some cases, the squirrel monkeys even performed well when three numerals had to be added together to generate the overall number of food items in that choice set. Thus, monkeys summed the values of Arabic numerals in this test.

Such performances are not limited to nonhuman primates. A parrot named Alex also showed evidence of performing addition when presented with sequential sets of items that he had to label with a verbal Arabic numeral (e.g., Pepperberg 2006). Alex was asked, “How many total X?” before he was shown two sets of items such as jelly beans or nuts. The sets were presented sequentially, so he could never see all items at once. Instead, he had to combine the sets in order to label them properly. He performed well in most cases, also suggesting a parallel to the ability of young children to begin to be able to add sets. This ability to accommodate different arithmetic operations may emerge very early in the lives of animals as well, with newborn chicks showing some capacity for accommodating addition and subtraction operations on sets of items they see move behind an occluder (e.g., Rugani et al. 2009).

The basis for nonhuman animal arithmetic competencies such as those described above comes from their ability to represent quantity, albeit inexactly. Gallistel and Gelman (1992) suggested that a preverbal counting model may account for numerical understanding in the absence of language and that this mechanism is used both by young children and by nonhuman primates. This *accumulator* model, originally developed by Meck and Church (1983), posits that “pulses” are passed, regulated by a gate, with one-for-one correspondence to the objects

or events being counted to an *accumulator* which sums the value and sends it to memory to allow for comparison to other values. Such a mechanism could allow an animal to add sets of items to its representation of the summed total of a set, and some studies have shown that animals seemingly do combine item-by-item serially presented sets into a summed total. For example, Beran (2004) adapted the “summation” test of Rumbaugh et al. (1987) to present chimpanzees with an item-by-item summation task in which each item was added to a nonvisible final set quantity varying in both set size and difference between sets. Chimpanzees were adept at choosing the larger number of summed items in this type of discrimination (also see Hanus and Call 2007). These results offered support for the *accumulator* model, due to a decrease in performance when the difference between sets was small and when overall magnitudes were larger compared to when they were smaller.

Addition by animals also can be approached in other ways, such as by assessing whether nonhuman primates can sum two sets presented in full (rather than one-by-one) on a computer screen. Such approaches are appealing because they can be used comparably across species, and they can control many stimulus features that are confounded with number of items, such as density, total area, and others. For example, Cantlon and Brannon (2007) presented monkeys and college students with trials in which the participants first saw arrays of dots in succession that they had to combine even though they never saw all items at once. Then, they had to choose from two options the array that most closely approximated the sum of the previous arrays. This required them to view two smaller sets, combine them into a representation of the total, and then match that total. Monkeys’ performance closely mirrored that of the human participants, and these results suggested that nonhuman primates are capable of numerical computation in the absence of symbolic representation and that monkeys share similar arithmetic-processing mechanisms with humans.

The study of addition in children and nonhuman animals offers many avenues to answer questions about the development of more

advanced human mathematical abilities. A comparative approach, with nonhuman primates and other animals, also offers potential answers regarding the origins and mechanisms behind arithmetic fluency and the understanding of operations such as addition. A complete understanding of addition, structurally, behaviorally, and developmentally, serves to improve interventions for mathematical education and for aiding those that struggle with learning arithmetic and other mathematical operations.

## Additive Genetic Variance

Vertika Singh<sup>1,2</sup> and Kiran Singh<sup>1</sup>

<sup>1</sup>Department of Molecular and Human Genetics, Banaras Hindu University, Varanasi, India

<sup>2</sup>CSIR-Central Drug Research Institute, Lucknow, India

## Definition

Additive variation is the total effect on a trait stemming from one or more gene loci. Each locus contributes to the trait in a measurable way.

## Introduction

Within a population, there are numerous potential sources of phenotypic variations. Each of these sources signifies a distinctive underlying origin.

These sources of phenotypic variations decide whether that trait has an evolutionary potential and holds an ability to respond to natural/artificial selection or whether it can respond to environmental variations. A large number of investigators across the world are engaged in determining the significance of both the genetic and environmental factors in regulating the phenotypic expression of a particular trait. These types of information will help them in predicting the evolutionary dynamics of a whole population with reference to a particular trait (Waldmann 2001; Fisher et al. 2004; Byers 2008; Saastamoinen 2008).

### Phenotypic Variance

Phenotypic variability ( $V_P$ ) within a population occurs because of two major components which are additive. These are genetic variance ( $V_G$ ) and environmental variance ( $V_E$ ). This relationship is summarized as (Falconer and Mackay 1981; Lynch and Walsh 1998; Byers 2008):

$$V_P = V_G + V_E$$

However, recently with the evolution of epigenetics, the equation is modified as:

$$V_P = V_G + V_E + V_{GE}$$

where  $V_{GE}$  stands for variance associated with the interaction of genetic and environmental factors.

The genetic variance ( $V_G$ ) can be further subdivided into three types, i.e., (1) additive genetic variance, (2) dominance variance, and (3) epistatic variance.

Additive genetic variance occurs due to genes which show an additive effect on the quantitative trait. This results in deviance from the mean phenotype due to inheritance of a particular allele and its relative effect on phenotype. It measures the magnitude to which individual phenotype differences can be prophesied due to additive effects of allelic substitutions.

Dominance genetic variance, on the other hand, is associated with dominant gene actions which cover the influence of the recessive alleles at the particular locus. Epistatic genetic variance

occurs due to statistical interaction among loci, i.e., gene-by-gene interaction. The genetic basis of this variance is epistasis, and it is called the **interaction genetic variance** ( $V_I$ ).

### Heritability

Heritability refers to the proportion of phenotypic variance due to additive genetic variance among individuals. It is often measured as a fraction of the total variance for the trait that is genetic.

The equation can be given as:

$$H = V_G/V_P$$

where **H** stands for heritability.

It should be noted that here H does not define the fraction that is genetically determined but the fraction of the variability that is genetic. It is worth noticing that in the absence of genetic variation (every individual with the same genotype),  $V_G = 0$ , and hence **H** = 0. Contrariwise, if there is no environmental variability (everyone is subjected to same environmental effects), then  $V_E = 0$  or  $V_G = V_P$  and, therefore, **H** = 1. These values are the theoretical parameters for the H. However, for a polygenic trait, H value would lie somewhere between 0 and 1.

For example, if two inbred lines of beans are intercrossed, in the F1, the variance in bean weight is measured as 1.5. The F1 is self-crossed; in the F2, the variance in bean weight comes out to be 6.1. If we have to estimate the broad sense heritability of bean weight in the F2 population, it can be calculated as:

As the variance in F1 is all environmental and variance in F2 is environmental and genetic, therefore:

$$V_E = 1.5, V_P = 6.1; \text{ therefore, } V_G = 6.1 - 1.5 = 4.6.$$

And heritability of bean weight can be calculated as **H** =  $V_G/V_P$ , i.e.,  $4.6/6.1 = 0.754$ .

## Adjunctive Behavior

### ► Schedule-Induced Behavior

## Adolescence

Naomi D. Harvey  
School of Veterinary Medicine and Science,  
The University of Nottingham,  
Sutton Bonington, UK

## Synonyms

Juvenile period; Pubescence

## Definition

The stage in human and nonhuman animal development through which a juvenile becomes a reproductively and behaviorally mature adult.

## Introduction

Adolescence is a developmental stage in an animal's life history that is characterized by both reproductive and behavioral maturation. The terms “puberty” and “adolescence” are often used interchangeably as synonyms. However, it is more accurate to consider adolescence as the period in which an animal transitions into an adult that is reproductively, socially, and cognitively mature (Sisk and Foster 2004), encompassing puberty, which more precisely is the process through which an individual becomes reproductively mature. Specialists in this area argue that reproductive (gonadal) development and behavioral development are distinct processes, driven by separate neurobiological mechanisms, that are linked by interactions between gonadal steroid hormones and the nervous system (Sisk and Foster 2004).

Adolescence is a period that is typically associated with marked changes in cognition and social behavior that include a weakened ability to regulate affect and behavior, increased reactivity to stressors, an increase in risk-taking behavior, and a greater social awareness (Crone 2009; Spear 2009; Steinberg 2005). These changes in behavior and cognition could be thought of as forming two distinct categories, primary and secondary. Primary changes contribute directly toward maturation, such as improvements in executive function, and development of sexual behavior. The reorganization of neural circuitry and increase in gonadal steroid hormones required to enact the primary changes lead to temporary secondary changes associated with psychological vulnerability such as increased sensitivity to stressors, increased risk-taking behavior, and weaker regulatory control of behavior and affect (Schulz and Sisk 2016; Steinberg 2005).

Although all vertebrate species undergo a period of transition to become reproductively and behaviorally mature (Ball and Wade 2013), mammalian species, particularly primates and rodents, are the dominant focus in scientific literature on this period of development.

## The Role of Hormones in the Onset of Puberty

In primates and sheep, the hypothalamic-pituitary-gonadal (HPG) axis (comprising the hypothalamus, anterior pituitary, and gonads) is active during prenatal life and infancy, is suppressed during a prepubertal period of development, and then reactivates and matures throughout puberty resulting in reproductive maturation (Delemarre-Van De Waal 2002; Plant 2015; Plant and Zorub 1982). The HPG axis reactivates when gonadotropin-releasing hormone (GnRH) is secreted by the hypothalamus following stimulation by the neuropeptide kisspeptin (Clarke et al. 2015; Irwig et al. 2004). GnRH is released into the blood stream in pulses and stimulates the secretion of two gonadotrophins, luteinizing hormone (LH) and follicle stimulating hormone (FSH), from the anterior pituitary gland. Gonadal development is triggered by this release of LH and FSH, which stimulates ovarian follicles to produce estrogens and progesterone, as well as stimulating the Leydig cells in the testis to produce testosterone.

In contrast to primates and sheep, which experience an extended window of prepubertal development and reactivation of the HPG, spermatogenesis in rats and hamsters begins shortly after birth at days 5 and 9, respectively (van Haaster and de Rooij 1993), and the rise in pubertal hypothalamic activity in rodents is not thought to be part of a reactivation of the HPG axis (Plant 2015).

While puberty is associated with clear physiological markers, adolescence is a period of gradual change, and there are no distinct physiological markers that indicate its beginning and end. In rats, the window within which adolescence occurs is widely considered to be days 28–42 after birth, with adulthood being reached by day 60, while some use a less conservative classification and consider adolescence to occur between days 21 (the typical onset of weaning) to 59 (McCormick and Mathews 2010). Although adolescence in humans is typically thought of as occurring during the teenage years, hormonal and organizational brain changes begin between 9 and

10 years in females and 10 and 12 years in males (Peper and Dahl 2013). The visible signs of puberty typically thought to signal its onset (such as onset of menarche in females, pubic hair growth, and sexually dimorphic physical changes) actually occur toward the final stages of puberty. If we define human adolescence as beginning and ending according to the maturation of the brain, then this period of human development could be considered to begin around the age of 10 and cease in the mid to early 20s (Sisk and Zehr 2005).

## Neurological Development in Adolescence

Steroid hormones have two methods of action in the nervous system: activational or organizational. The activational effect of steroid hormones is temporary and typically associated with the adult response to its presence or absence (Sisk and Zehr 2005). Of most relevance to adolescence is the organizational effect that steroid hormones play in reorganizing the nervous system, which is a permanent change. There is a large body of evidence indicating that neurological development continues throughout adolescence. In both human and nonhuman animals, reorganization of neural circuitry occurs during adolescence, using many of the same processes involved in the original formation of the nervous system, including programmed cell death (apoptosis), neurogenesis, dendritic pruning, and sexual differentiation (Schulz and Sisk 2016). The structural changes associated with this adolescent neural reorganization are sex and brain region specific (Sisk and Zehr 2005).

In addition to reorganization and activation of the neural circuits associated with reproductive behavior, regions of the mammalian brain associated with emotional regulation, behavioral inhibition, and risk/reward judgments are especially impacted by changes in brain structure and function (Steinberg 2005). Areas of the medial and dorsal prefrontal cortex and the ventral prefrontal cortex are integral to cognitive regulation of goal-directed behavior and affective response

(Nelson et al. 2005). Adolescent developmental changes in these areas involve pruning and increased myelination of synaptic networks responsible for social cognition and appear to be driven by gonadal-independent development (Nelson et al. 2005). The regions of the brain associated with affective responses to rewards and punishers include the nucleus accumbens, amygdala, and hypothalamus, and in contrast to those brain regions responsible for cognitive regulation, these regions are heavily imbued with gonadal steroid receptors which moderate considerable reorganization during puberty as a result of gonadal development (Nelson et al. 2005). However, adolescent reorganization of the regions necessary for the expression of reproductive behavior is activated both by gonadal steroid hormones and unknown gonadal steroid-independent mechanisms (Sisk and Foster 2004).

That some aspects of neurological remodeling of the adolescent brain can occur independently of gonadal maturation highlights the fact that reproductive and behavioral maturation are distinct, though entwined, processes (Sisk and Foster 2004). For example, the ability to express reproductive behavior in hamsters is reliant upon both gonadal maturation and steroid-independent adolescent maturation, as copulatory behavior can be artificially triggered by testosterone in castrated hamsters after puberty (Schulz et al. 2004), but not before (Romeo et al. 2002). Indeed, that puberty and adolescence are linked but not the same thing has considerable consequences for long-term behavioral outcomes of hormone-brain interactions when the timing of pubertal and non-pubertal changes during adolescence differ.

The timing of gonadal maturation in mammals can be impacted by a number of extrinsic factors, including calorie intake, calcium levels, extreme exercise, and even the quality of the infant-parent relationship and familial stress (Belsky et al. 2010). A mismatch in the timing of gonadal maturation and adolescent brain reorganization could have considerable effects on individual differences and risk of psychopathologies in adulthood (Sisk and Zehr 2005), and further research on the behavioral outcomes of hormone-brain

interactions during puberty and adolescence is warranted (Sisk and Foster 2004). In human females, early gonadal maturation has been consistently associated with greater risks of clinical depression and eating disorders, in addition to problems with substance use (Golub et al. 2008); however, these results are confounded by problems of study design and are associations, not causation, so may be caused by correlations with unaccounted for confounding variables such as familial stress.

### **Differences in Cognition and Behavior During Adolescence**

Adolescence triggers the emergence of considerable behavioral changes as the juvenile animal develops into the adult. Some of these changes are associated only with the adolescent phase, while others are permanent. Some of the most distinct changes are the emergence of reproductive behavior, agonistic and impulsive behavior and stress reactivity.

In rodents, the emergence of reproductive behavior occurs 1–2 weeks after pubertal testosterone increases in males and 1–2 weeks after vaginal opening in females (Sisk and Zehr 2005). To elicit reproductive behavior, the maturation of the gonadal axis alone isn't enough. Steroid-independent and steroid-dependent organizational changes in the brain are required during adolescence to enable these behaviors to be activated by gonadal steroid hormones and to function without impairment. Indeed, if gonadal hormones are absent during adolescent neurological development, it can cause long-lasting impairments to reproductive behavior (Sisk and Zehr 2005). Examples of typical reproductive behaviors in mammals that are activated by the presence of gonadal hormones after adolescent remodeling include mounting and lordosis (presenting to indicate sexual receptivity). The influence of pubertal gonadal hormones on the reproductive behavior of an animal depends on the species, sex, and timing of exposure.

Development of other adult behavioral patterns, in addition to reproductive behavior, also

relies on the organizational effect of gonadal hormones. A traditional behavioral test for measuring anxiety is the open-field test, in which lower levels of activity are interpreted as reflecting greater levels of anxiety. Adult male rats are typically less active in an open-field test than adult females, and they display less social behavior in novel environments. These differences emerge during puberty and can be prevented by castration and reinstated by replacement of testosterone during puberty. Such findings clearly demonstrate the organizational effect of gonadal hormones on these anxiety-related behaviors (Schulz et al. 2009). Comparatively, gonadal hormones expressed during puberty have also been shown to have a significant organizational impact on the development of spatial cognition via studies of people with naturally occurring disorders of the HPG axis (Sisk and Zehr 2005). Specifically, the lack of gonadal hormone expression during the normative puberty age window leads to impairments in spatial cognition in adults that cannot be repaired by administration of gonadal hormone treatments after the age of 20. Flank rubbing in Syrian hamsters and territorial scent marking in tree shrews during male-male interactions are further examples of behavior that emerges during adolescence due to gonadal hormone-dependent reorganization (Sisk and Zehr 2005).

Adolescent rats show distinct adolescent-phase differences from adults in learning and memory that stem from extensive changes to the neural circuitry that mediate these processes during adolescence (McCormick and Mathews 2010). The regions of the brain that mediate the majority of learning and memory are the medial prefrontal cortex, amygdala, and hippocampus, all of which have dense corticosteroid receptors and are influenced by glucocorticoids. An example of the differences between adolescent and adult rats is the higher thresholds for tolerating aversive motivational learning exhibited by adolescent rats when compared to adults (Pautassi et al. 2008). Differences have also been demonstrated in the responses of adolescent rats to fear conditioning that imply ongoing development of the amygdala and hippocampus (McCormick and Mathews

2010). At least part of these differences in learning and memory in adolescents can be attributed to differences in the experience of stress by adolescents, impacting performance on tasks involving a stress component.

Prepubertal rats exhibit activation in response to anxiogenic drugs in the nucleus accumbens, part of the ventral striatum, while postpubertal rats exhibited activation predominantly in the prefrontal cortex (Lyss et al. 1999). It is therefore not surprising that stress-related behavior in rats differs significantly between adolescents and adults, given the developmental processes occurring in the limbic and prefrontal areas (Spear 2009). Further discussion of differences in stress response of adolescents will be described below in reference to adolescence as a sensitive period of development.

### **Adolescence as a Sensitive Period of Development**

As stated previously, adolescence involves considerable reorganization of the brain's neural circuitry that can occur independently of gonadal reproductive maturation during puberty. Because the organizational effects of gonadal hormones on adult behavior are only possible during the adolescent period of development, adolescence is considered to be a sensitive period for neurological development. However, even if these changes occur at the correct times, the changes themselves are associated with additional psychological vulnerability in adolescents such as increased risk-taking behavior, weaker regulatory control of behavior and affect, and increased sensitivity to stressors (Schulz and Sisk 2016; Steinberg 2005).

Spear (2000) proposed a hypothesis that the organizational changes associated with adolescent neurological remodeling lead to increased stressor reactivity via the hypothalamic-pituitary-adrenal (HPA) axis, which in turn increases the risk of developing psychopathologies in vulnerable individuals. In order to evaluate this hypothesis, it is vital to understand the role of adolescence in

normally developing children, to determine whether changes in stress physiology and emotional reactivity are indeed characteristic of the transition from childhood to adolescence (Spear 2009). A set of seminal experiments published in a special edition of *Developmental Psychology* in 2009 focused on stress reactivity and emotional sensitivity during the transition into adolescence provide just such evidence.

Gunnar et al. (2009) examined 82 children between the ages of 9 and 15 years, recording baseline and stressor levels of salivary cortisol as a marker of HPA activation, pubertal development status, self-reported stress, and cardiac measures of sympathetic and parasympathetic activity (Gunnar et al. 2009). The results of their study indicate clear changes in the activity of the HPA axis as children transition into adolescents, observing developmental increases in cortisol under both baseline and stressor conditions. The increase in basal cortisol observed by Gunnar and colleagues was found to be associated with puberty, as opposed to simply being age-related. Their findings were strikingly similar to those of Stroud et al. (2009), who using similar psychophysiological methods were also able to provide evidence for puberty-related hyperresponsiveness to stressors (Stroud et al. 2009). Differences in baseline cortisol levels due to maturation in adolescents highlight the importance of ascertaining pre-challenge baselines of any measures being used prior to implementing challenges in behavioral tests.

It has been suggested that, in humans, this normative developmental increase in reactivity in the HPA axis and autonomic nervous system could promote a shift toward dysregulation of the stress response in at-risk individuals, leading to the development of clinical psychopathologies such as depression (Spear 2009; Stroud et al. 2009). This hypothesis promotes the consideration of adolescence as a sensitive period in which experiences during this time can have long-term impacts on an individual's behavior and cognition. Evidence for just such an effect can be found in studies using animal models, such as the work of Chaby and colleagues

(Chaby et al. 2013) who tested the impact of chronic unpredictable stress experienced by adolescent rats on their long-term cognitive bias, decision-making, coping response, and exploratory behavior. Their results showed that unpredictable stress experienced during adolescence has lasting effects on cognition and behavior of rats, which exhibited greater sensitivity to reward loss and a negative cognitive bias lasting into adulthood. Such results support the notion that chronic unpredictable stress experienced during adolescence can induce long-term negative affective states, which is likely in turn to impact upon a suite of differences as adults in cognition and executive function inducing biases in decision-making, attention toward negative stimuli, judgment, and memory (e.g. Paul et al. 2005; Shields et al. 2016). Such negative cognitive biases could have adaptive ecological significance, if, for example, an animal inhabits an area with high-predation levels (Chaby et al. 2013); however, for humans and captive/companion animals that live outside of typical ecological niches, these stress-induced alterations could have long-term detrimental impacts on their emotional and behavioral well-being.

## Conclusion

Adolescence is a period of dramatic neurological development that is organized by both gonadal and non-gonadal hormone pathways. This period encompasses puberty, with adolescent changes typically beginning long before physiological signs of puberty are apparent and ending long after reproductive maturity is reached. Significant remodeling of the brain's neural circuitry during this period has both short-term and long-term impacts on behavior and cognition that characterize adolescence as a sensitive period in development. Studies involving adolescent animals should take into account possible normative differences in basal levels for all response variables and consider the potential long-term impacts of testing on individual differences. Furthermore,

attention should be paid to this period of development by pet owners, as chronic stress experienced during adolescence could shape stress reactivity later in life.

## Adrenalin

Reema Chaudhary

Molecular Biology Division, Bhabha Atomic Research Centre, HBNI, Mumbai, India

## Synonyms

Epinephrine

## Definition

Adrenalin is a hormone and neurotransmitter which is secreted by the adrenal glands and certain neurons in response to panic, threat, or fear (fight or flight response). Stress is another stimulus for secretion of this hormone.

## Adrenal Glands

The paired glands located superior to each kidney in the retroperitoneal space are called adrenal (suprarenal) glands. The adrenal glands divided into two structurally and functionally distinct regions which are as follows:

- Adrenal cortex, which comprises 89–90% of the gland and located peripherally.
- Adrenal medulla, which is small and centrally located.

A connective tissue capsule covers the gland. The adrenal glands are richly supplied with the blood flow. Steroid hormones are produced by the adrenal cortex which is essential for maintaining electrolyte balance in the body. Complete loss of adrenocortical hormones lead to death due to dehydration and electrolyte imbalance in a few days to week which can be treated only by hormonal therapy. The adrenal medulla produces three catecholamine hormones – norepinephrine

(noradrenaline), epinephrine (adrenalin), and a small amount of dopamine.

## Adrenal Cortex

The adrenal cortex is subdivided into three zones which are as follows:

*Zona glomerulosa*: This outer zone lies deep to the connective tissue capsule and composed of cells which are closely packed and arranged in spherical clusters. These cells secrete hormones called mineralocorticoids because they affect mineral homeostasis.

*Zona fasciculata*: It is the middle zone and widest of the three zones and consists of cells arranged in long and straight columns. Glucocorticoids are mainly secreted by these cells and maintain glucose homeostasis.

*Zona reticularis*: This is the inner zone and consists of cells which are arranged in branching cords and synthesize small amounts of weak androgens having masculinizing effects.

## Adrenal Medulla

This is the inner part of the adrenal gland which is a modified sympathetic ganglion of the autonomic nervous system (ANS). It develops from the same embryonic tissue as all other sympathetic ganglia, but its cells lack axons. The cells of the adrenal medulla which secrete hormones are called as chromaffin cells.

The two major hormones synthesized by the adrenal medulla are epinephrine and norepinephrine (NE), also called as adrenaline and noradrenaline, respectively.

## Physiological Effects

It acts by binding to different adrenergic receptors ( $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$ ) of the sympathetic nervous system. Cannon (1931) proposed the idea of involvement of adrenal medulla and sympathetic nervous system in fight, flight, and fright

response. The responses to adrenalin stimulation are as follows:

- Stimulation of  $\alpha$ -adrenergic receptors leads to increased glycogenolysis (Arnal et al. 1986) in the liver and muscle, and glycolysis in muscle.
- Stimulation of  $\beta$ -adrenergic receptors leads to enhanced lipolysis in adipose tissue, adrenocorticotrophic hormone (ACTH) secretion from the pituitary gland, and increased cardiac output.

## Biosynthesis

It is synthesised in the adrenal medulla in an enzymatic pathway shown in Fig. 1. Precursor molecule of adrenalin is tyrosine which further oxidized to L-3, 4-dihydroxyphenylalanine (L-DOPA). Decarboxylation of L-DOPA gives dopamine which is converted to norepinephrine by dopamine  $\beta$ -hydroxylase. The last step is the methylation of the primary amine of norepinephrine, catalyzed by the enzyme phenylethanolamine N-aminotransferase (PNMT). S-adenosylmethionine (SAME) acts as the methyl donor. PNMT is mainly found in the chromaffin cells and in brain, but in very small amounts. In 1953, Coupland suggested that the adrenal cortex secreted a “methylation factor” that influenced the N-methylation of norepinephrine to form epinephrine. In 1959, Kirshner identified the adrenomedullary enzyme, PNMT (phenylethanolamine N-methyltransferase),

**Adrenalin, Fig. 1** The enzymatic pathway for synthesis of epinephrine (adrenalin)

responsible for the synthesis of epinephrine from norepinephrine.

## Regulation

The expression of PNMT is dependent on high concentrations of adrenocortical glucocorticoids (Wurtman and Axelrod 1965) which are released from the adrenal cortex that reach the medulla via an intra-adrenal portal vascular system. In the adrenal medulla, these glucocorticoids regulate PNMT in two ways, transcriptionally and post-translationally, by regulating the stability of the protein (Wong 2003). The levels of PNMT consequently affect the synthesis of adrenalin. In addition, epinephrine biosynthesis is activated by neural stimuli through the splanchnic innervation of the gland.

PNMT expression along with glucocorticoid levels were thought to be an important factor in defining the fate of undifferentiated cells as chromaffin cells but not as neurons. Recently, it has been observed that glucocorticoids receptor-deficient mice develop normal numbers of chromaffin cells, indicating that glucocorticoid signaling is not essential for forming the neuroendocrine phenotype in chromaffin cells and suggesting involvement of other factors (Huber et al. 2002).

Stress is also considered to be another stimulus for production of adrenalin. The main components of the stress system are hypothalamic CRH, as well as locus cereleus-norepinephrine and autonomic systems and their peripheral effectors. Thus, response of the endocrine system to stress is characterized by activation of the HPA axis and the sympathetic adrenomedullary system, which is associated with hypersecretion of adrenal hormones, particularly glucocorticoids and epinephrine (Pervanidou and Chrousos 2007). Production of adrenalin is stimulated by increasing the activity of tyrosine hydroxylase and dopamine  $\beta$ -hydroxylase which are key enzymes involved in catecholamine synthesis.

The reaction of the adrenal gland to stress has been studied in different animal models, using, for example, immobilization stress or cold stress where the release of catecholamines is stimulated

by the splanchnic innervation of the gland (Ehrhart and Bornstein 2008).

In stress conditions, adrenal cortex is stimulated by ACTH to release cortisol which consequently increases the expression of PNMT enzyme in chromaffin cells.

Chromaffin cells also possess nicotinic acetylcholine receptors which bind to acetylcholine resulting in depolarization of the cell and influx of calcium through voltage-gated calcium channels. Increased levels of calcium in the cells trigger the exocytosis of chromaffin granules, hence increasing the level of adrenalin in the bloodstream.

Adrenalin does not exert negative feedback regulation unlike other hormones. Its action is terminated with reuptake into nerve terminal endings, some minute dilution, and metabolism by monoamine oxidase and catechol-*O*-methyl transferase.

## Conclusion

Adrenalin is a key hormone playing role in flight or fight response. When brain senses some danger, adrenalin levels are elevated in bloodstream which is termed as adrenalin rush because its effects are executed very fast and once the danger is gone it may last up to an hour. To combat this hormone rush, “rest and digestive system” has to be activated which allows body to rest. There are medical conditions which results in overproduction of adrenaline such as surreptitious epinephrine administration, pheochromocytoma, and other tumors of the sympathetic ganglia.

## Synonyms

[Sensory and motor impulses](#)

## Definition

Neural impulses which travel from sensory organs/receptors to the central nervous system (CNS) are known as afferent impulses, whereas those which travel from the CNS to the organs/glands are known as the efferent impulses.

## Introduction

Those nerve cells which help in communication of action potentials (neural impulses) between the central nervous system and other body organs form the part of peripheral nervous system (PNS) (Baars and Gage, 2010). Depending upon the direction of this signal, neural impulses can be divided into two:

- (a) Afferent: neural impulse carries signals from sensory receptors or organs to the brain or spinal cord (CNS) for their further processing/analysis and
- (b) Efferent: neural impulse carries signals from brain or spinal cord (CNS) to the organs (like limbs, muscle, glands, etc.) for displaying proper reaction.

Due to their function, nerve fibers which carry afferent impulses are known as afferent nerves or sensory nerves, and those nerve fibers which carry efferent impulses are known as efferent nerves or

### Afferent and Efferent Impulses, Fig. 1

Afferent and efferent nerve fiber  
(Image adapted from:

motor nerves. On the other hand, the neurons which connect sensory nerves and motor nerves are known as interneurons or association nerve cells (Fig. 1).

### General Description

Both afferent and efferent terms have been derived from French. Afferent from *ad ferens* (Latin *ad* literally means **to** and verb *ferre* means **bring**) = **bring towards**, and efferent from *ex ferens* (Latin *ex* means **from** and verb *ferre* means **carry**) = **carrying away**.

The PNS gathers information from the environment and directs it towards the CNS; the CNS processes this information and directs it back to the PNS for suitable reaction. For example, when you accidentally touch a hot iron-press, the heat sensation is transmitted by the peripheral nerve to the spinal cord (afferent impulse), upon which spinal cord sends back signals through the nerves to the limb to initiate some motor action like to withdraw your limb or to push away the iron-press (efferent impulse). (Ganong, 2005) In former case, sensory neurons are involved; whereas in

latter case, motor neurons execute the desired actions. The sensory neurons receive a wide variety of stimuli such as taste, smell, light, pain, etc. through different senses and sends these signals upwards through the nerves to reach in the CNS. Hence, these are also known as afferent or ascending pathways. The motor neurons form the efferent or descending pathways as they pass the signals along the nerves to the effector organ, which are primarily the muscles and glands (Fig. 1).

As evident from fig. 1, there is structural difference between afferent and efferent neurons. Afferent impulses are transmitted by pseudo-unipolar nerve cell, that is, it contains a soma with long axon that splits into two branches; one branch runs to the periphery and the other toward the spinal cord. Therefore, no dendrites are present in this case. The soma of efferent neuron is satellite shaped and consists of several shorter dendrites projecting out of it along with a long axon. This axon generally forms a neuromuscular junction with the effectors. (Dharani, 2015) The motor neuron is present in the grey matter of the spinal cord and medulla oblongata and forms an electrochemical pathway to the effector organ or muscle.

Introduction

Animals engage in social activities that can be affected by the simple presence of other individuals around them. In some cases, the presence of others may facilitate positive social interactions – also called affiliative behaviors – but in other cases, may constrain them perhaps by increasing aggressive behaviors. The way that individuals interact affiliatively with others is based on several factors like age, sex, kinship, and ecological conditions. Affiliative behaviors are important in maintaining group cohesion and increasing individual fitness in different animal species. The particular functions of affiliative behaviors vary among species, type of behavior, age, and sex.

Affiliative Behaviors

Through affiliative behaviors, animals can display a wide range of interactions, either intra- or interspecifically. An affiliative behavior is often defined as friendly and peaceful acts exchanged among individuals. Affiliative behaviors occur across a wide variety of taxa, but are particularly common among birds and mammals, and are often found within the category of social interaction. In the order Primates, for example, individuals dedicated less than 10% of their activity budget to social activities (60 primate species from 28 genera), and affiliative behaviors account for more than 80% of all social interactions (Sussman et al. 2005). The types of affiliative behaviors vary between species. For example, in mammals, affiliative behaviors are classified as grooming (either cleaning skin and hair among individuals or engaging in gestures related to cleaning); spatial proximity (referring to the

distance among individuals); approaching (individual approaches to one or more other individuals); social play (two or more individuals exchange in a suite of behaviors that may be practiced for more costly behaviors such as mating, fighting, or fleeing for a certain period of time); touching (any body part of individuals are in contact briefly); hugging (individual places its arms around the body of the receiver); and food sharing (transfer of food among individuals). Other taxon-specific affiliative behaviors in mammals are exhibited like synchronous swimming and contact behaviors in dolphins (Clegg et al. 2017) or greet (sniff or touch noses) and head on neck or back (head resting on the neck or back of other animals) in the wild ass (Asa et al. 2012). Birds also interact affiliatively to each other through allopreening behaviors that correspond to allogrooming (mutual grooming) in mammals and consist of involved individuals cleaning body parts that cannot be cleaned by self-preening. Other affiliative behaviors that have been reported for birds are sitting within reaching distance, social play, and invite preening (Braun et al. 2012).

The study of affiliative behaviors allows determining the degree of affiliation, affiliative relationship, sociality index, and the establishment of social bonds among members of the group (see affiliative bond). Before estimating any measure of affiliation between individuals, it is necessary to collect behavioral data from the studied animal. Martin and Bateson (2007) provide different recording methods that can be used in the study of affiliative behaviors like ad libitum sampling, focal animal sampling, and scan sampling. Affiliative behaviors can be recorded as the duration or frequency that individuals were in contact, huddling, grooming, or engaged in any other affiliative behavior.

## Factors That Influence Affiliative Behaviors

The expression of affiliative behaviors among individuals depends on several factors such as

biological (age, sex), social (hierarchical rank, kinship), hormonal, and ecological conditions. It is hypothesized that individuals may interact affiliatively with other individuals of similar age-sex class such as immature with immatures, female with females, and male with males. In some species, females are more likely to engage in affiliative behaviors to form alliances and gain support during harassment (such as by high-ranking individuals) and during competition or infant care (Connor et al. 2006). In species with female-biased dispersal, males exchange affiliative behaviors (e.g., approach, embrace, arm wrap, and groom) with one another more than with females. Males form strong bonds with one another through affiliative behaviors for inter-community territorial display, boundary patrols, and raids into the neighboring territory to defend or gain access to females (Slater et al. 2009).

On the other hand, members of different age-sex classes can engage in affiliative behaviors. For example, in primates, adult males interact affiliatively with younger individuals maybe to reduce physiological stress (Bardi et al. 2017), to increase mating opportunities (developing affiliative relations with females), or to enhance greater spatial centrality in the group and, consequently, enhance predator protection (Gould 1997). However, immatures can benefit from affiliation with adult males to enhance predator detection, alloparental care, and opportunities to develop social skills (Gould 1997). Females and males can also engage in affiliative behaviors as seen in birds; males engaged more in allopreening behavior with females than with other males. Allopreening between females and males has been associated with strengthening and maintenance of pair bonds between breeding partners as well as with parental cooperation over offspring care (Kenny et al. 2017).

Social aspects such as hierarchical rank also influence affiliative behaviors among individuals. In species characterized by a dominance hierarchy, individuals of the same dominance rank tend to engage more in affiliative behaviors compared to individuals of differing ranks. For

instance, high-ranking individuals are more often in proximity and engage more in grooming between each other than low-ranking individuals. However, this pattern is not always consistent since some subordinates tend to interact affiliatively with high-ranking individuals presumably to obtain benefits like gaining access to food resources that are monopolized and support in agonistic interactions (Seyfarth and Cheney 2012; Smith et al. 2007). In hyenas, the social rank of males and females influences the association between them. Both high- and middle-ranking males associated most closely with high-ranking females (Szykman et al. 2001).

Genetic relatedness between group members is also a critical parameter that influences affiliative behavior. Kin-directed affiliative behavior is prevalent in social animals, and kin selection theory suggests that individuals enhance inclusive fitness benefits by biasing affiliative behavior toward relatives (Hamilton 1964). In particular, animals with high genetic relatedness engage affiliative behaviors more frequently than those with less genetic relatedness or nonrelatives (Smith 2014). The effect of kinship has been studied in birds in which preening bouts toward siblings are more frequent and of longer duration than toward non-siblings (Ju and Lee 2016). In species with female philopatry (an organism remains in its birthplace), like baboons, ground squirrels, and elephants, affiliative behaviors predominate between females compared to males (Lawson Handley and Perrin 2007). The establishment of social bonds with kin females, through affiliative behaviors, can reduce levels of aggression among them, increase levels of care for dependent young, decrease the cost of maternal investment, and reduce the risk of infanticide or predation (Silk 2007). In species with male philopatry (e.g., chimpanzees and dolphins), affiliative behaviors predominate among males compared to females, allowing them to increase access to territory and opportunities of mating (Lawson Handley and Perrin 2007).

Kin selection also provides an explanation of cooperative breeding and associated affiliative

behaviors between relatives. Cooperative breeding is widely recognized in social insects, birds, mammals, and fish. Under the cooperative breeding context, helper individuals preferentially provide care to close kin enhancing the fitness of all individuals involved. These actions that benefit other individuals, like helping behaviors toward others, sharing resources, and cooperating, are called prosocial behaviors. The prosocial behavioral repertoire is diverse, involving various forms of affiliative behaviors, and it can be seen across different animal species (Dugatkin 2013; Rault 2019). Kin selection theory explains prosocial behavior toward kin. Additional examples of this behavior between relatives involve self-sacrifice by parents to benefit their offspring or help close kin. However, prosocial behavior cannot be explained entirely by kinship because several animals that are not genetic relatives cooperate with each other in many contexts. For example, vampire bats share part of their blood meal to hungry conspecific, or female elephants help raise the offspring of other group mates (Dugatkin 2013). Reciprocal altruism theory (Trivers 1971) explains why an individual tends to behave cooperatively with nonkin. This theory suggests that individuals who cooperate and help others would increase the possibility of being helped in return.

Hormone levels are also important for affiliative behaviors. Oxytocin and vasopressin (vasotocin for nonmammalian vertebrates) are two neuropeptide hormones that modulate affiliative behaviors across vertebrate taxa. For instance, the hormone oxytocin promotes affiliative behaviors important in the formation and maintenance of cooperation, social bonds, and group cohesion (De Dreu 2012). Thus, individuals exposed to oxytocin increase food sharing and allogrooming in vampire bats (Carter and Wilkinson 2015) and social play in domestic dogs (Romero et al. 2015). Vasotocin is a hormone found in nonmammalian vertebrates, and it is a homologue of vasopressin in mammals. The hormone vasotocin plays an important role in the social development in birds. Chicks exposed to

this hormone increase affiliative interest (e.g., proximity, vocal communication, and contact behaviors) in parents through development, and males increase time spent in proximity with opposite sex conspecifics as they mature (Baran et al. 2016).

The ecological conditions in which individuals live impact the quantity and quality of the affiliative behaviors. In particular, habitat quality, space availability, food availability, resource distribution, or risks influence this behavior. For example, in poor-quality habitats with low food availability, individuals decrease affiliative behaviors like social play as an energy-saving strategy or due to a constrained activity budget under this condition (Nunes et al. 1999; Stone 2008). Similarly, grooming has been linked to variations in food availability; individuals groom more when food resources are abundant but diminish when food is limited (Defler 1995). Under space reduction of crowding conditions, some animal species adopt a conflict-avoidance strategy. This strategy consists of minimizing affiliative behaviors (e.g., social play and grooming) to decrease social interactions and the possibility for conflict due to forced proximity among individuals and limited escape opportunities (Judge 2000). On the other hand, there are cases in which animals increase affiliative behaviors (e.g., grooming) as a tension-reduction strategy. This strategy is used as a way to mitigate increased tension and reduce the likelihood of aggression when spatial density increases (Judge 2000). Finally, the risk that faces individuals in their habitats also regulates affiliative behaviors. For instance, animals engage in grooming under a situation of lower predation risk (Cords 1995) or decrease play in risky habitats in terms of injuries for individuals (Berger 1980).

## The Benefits of Affiliative Behaviors

Animals engage in affiliative behaviors because these provide them with several benefits. The benefits vary as a function of the type of affiliative

behavior that individuals perform as well as in function of the species, sex, and age of the partners. For example, grooming serves to remove dirt, flakes of dry skin, and parasites. Furthermore, grooming may help to establish and maintain affiliative relationships between individuals, which serve to protect them against competition with other group members. Additionally, individuals can use grooming as a currency to have access to resources or tolerance at feeding sites, reduce tension, or restore relationships after conflicts (Clutton-Brock 2016).

Social play is an important affiliative behavior in the development of young individuals. Through playing, individuals can acquire short-term and long-term motor and social benefits needed in adult life (Palagi 2018). Regarding social benefits, immatures, by playing, can acquire social skills like the ability to manage interactions with conspecifics, build social relationships, enlarge their social networks, and strengthen social bonds (Palagi 2018). In many species of animals, play continues in adulthood. Adults can use play in solving or preventing disputes, anticipating and buffering periods of social tension between unfamiliar partners, and increasing social tolerance (Palagi 2018).

Food sharing is considered affiliative behavior and is widespread in animals, including insects, birds, cetaceans, vampire bats, and primates. Some examples of food sharing include blood donations in vampire bats, sharing of meat and plant material in chimpanzees, and sharing food between adult lion tamarins, young ravens, and juvenile jackdaws. Food sharing is an important behavior because it helps to increase foraging efficiency, reduce predation risk or individuals may exchange food for grooming or support in a dominance conflict, and maintain coalitions (Stevens and Gilby 2004).

Coalitions between individuals are important in the establishment of communal signaling. Communal signaling is a form of communication in which males and females collaborate to produce visual and acoustic displays. In birds, females and males form coalitions that help to

establish communal signaling between them, which is important to defend home ranges, foraging territories, as well as positions in partnership of groups (Tobias et al. 2016).

## Conclusion

Affiliative behavior is present across a multitude of animal taxa. In general, affiliative behaviors in various forms provide several social benefits to manipulate situations, including formation of bonds that increase individual fitness. These kinds of social behaviors exist between relatives, mates, and nonrelatives and even among different species. Affiliative behaviors play an important role in the formation of bonds and alliances among individuals, favoring social integration, and are essential for maintaining complex social systems.

## Affiliative Bond

Leipzig, Germany

## Synonyms

[Affiliative relationships](#); [Pair-bonding](#); [Social bonds](#); [Social bonding](#)

## Definition

Long-term relationships of individuals, characterized by a high degree of proximity and high rates of friendly interactions, are termed affiliative or social “bonds.” The process by which such relationships are established and maintained is termed “social bonding.”

## Adaptive Significance

Evolutionarily, the oldest bond is probably that between mother and offspring, and emerged when postnatal maternal care became crucial for offspring survival. Mother-infant bonds are particularly important in species where offspring's dependence on the mother is a prolonged and energetically costly process, as in some birds and especially in mammals. In the latter, bonds between the mother and infant emerge during the earliest stages of ontogenetic development to facilitate nursing, and often, as in humans, extend well beyond the lactation period to ensure offspring's survival into reproductive age. In animals where successful rearing of the offspring depends on the investment of both sexes, as commonly seen in many bird species and some mammals, social bonds (termed “pair-bonds”) develop between a male and a female. Ensuring paternity, the need of joint provisioning of the offspring,

coordinated territorial defense, or protection of offspring against infanticidal males (i.e., males that kill other males' offspring) may ultimately be the reasons why males form long-lasting dyadic relationships with females in these animals.

Stable and long-lasting affiliative relationships also occur beyond reproductive units and are often forged between members of the same sex. Human social bonds are an example of such relationships, which are believed to be the basis of human hyper-cooperative nature most likely responsible for the biological success of our species. However, bonded relationships outside the context of reproduction also characterize other animals living in complex societies, such as dolphins, elephants, or nonhuman primates (hereafter: primates) (reviewed in Seyfarth and Cheney 2012). In primates, for example, groups consist of a relatively stable number of individuals, who rarely migrate. This allows group members to develop complex relationships with each other through frequent and repeated interactions. These interactions can be agonistic, generating dominance relationships, or affiliative resulting in bonded relationships. Both types of relationships serve primarily to cope with challenges associated with group living. In primates, an animal's behavior toward another individual often depends on the relationship of that individual with third parties, making the process of bond formation in these animals particularly intricate.

The adaptive benefits of social bonds in group-living animals have been explored to a considerable extent in baboons. In these primates, females remain in their natal group upon reaching sexual maturity and associate closely with related females mainly (e.g., with daughters and sisters) forming matriline. Interactions within and between matriline are influenced by clear dominance relationships, with lower ranking females being aggressed or displaced by more powerful females more often than vice versa. Female baboons form strong and durable bonds with few other females. It has been shown that females that form such relationships are characterized by increased longevity and offspring survival (Silk et al. 2010). This is likely because social bonds in

baboons mitigate the costs of group living in a species with a high degree of agonistic interactions between conspecifics. For example, by enhancing prospect of gaining coalition partners or tolerance from other individuals, affiliative bonds may provide protection from social conflict, or reduce stress associated with it, ultimately leading to higher longevity or offspring survival (Silk et al. 2010). These benefits of social bonds identified in baboons parallel those found in humans, where social support is positively associated with wellbeing, while social isolation is linked to impaired mental health and mortality. Studies on baboons reveal, therefore, that human social bonding is deeply rooted in the evolutionary past.

In some male-philopatric species, competition between males for social status and the associated reproductive benefits seem to be the main drivers for establishing male-male social bonds. In chimpanzees, for example, long-lasting bonded relationships between males are crucial for achieving and maintaining social status, which in turn is vital for gaining sexual access to fertile females (Muller and Mitani 2005). In contrast to female baboons, male chimpanzees often form durable bonds with unrelated group members. As in male chimpanzees, long-lasting social bonds found in dolphins also facilitate coalition formation between males to gain sexual access to females (reviewed in Seyfarth and Cheney 2012). Social bonds thus substantially contribute to reproductive success in group-living animals, by providing a supportive environment and/or by enhancing competitive potential of individuals forming them.

## Proximate Mechanisms

Social bonds have a strong physiological component, with endocrine system playing an especially important role in mediating them. Hormones, such as vasopressin, and neurotransmitters, such as endorphin, have been linked to mammalian social bonding. However, the neuropeptide oxytocin has received most scientific attention in this respect (reviewed in Crockford et al. 2014).

Oxytocin, which is produced in hypothalamus and released by the posterior pituitary into the blood, plays a vital role in stimulating birth and lactation. Facilitating nursing is an important function of mother-offspring bonds. There is hence no coincidence that a hormone involved in lactation also plays a crucial role in mediating mother-infant social bonds. Oxytocin released into the blood at birth, for example, facilitates olfactory infant recognition and triggers the onset of maternal care. Studies on several mammal species showed that infusion of this hormone facilitates, while blockage hampers, maternal behavior. This evolutionary ancient role of oxytocin in mediating mother-infant bonds was extended to facilitating other types of bonds in mammals. Most notably, oxytocin plays a pivotal role in social bonding between a male and a female. In mammals that form long-term male-female bonds, such as prairie voles or humans, the production of this hormone can be triggered by sexual intercourse or tactile contact and increases tolerance and rates of affiliative behavior between the two sexes. Importantly, oxytocin mediates social bonds between non-kin in group-living animals – evolutionarily the most recent type of bonds. In humans, for example, the administration of this hormone increases trust toward strangers. In chimpanzees, its production is elevated after grooming with a bonded partner or during between-group conflict to facilitate within-group affiliation – a pattern also observed in humans (Samuni et al. 2017). Thus, the effect of this hormone on social bonding extends well beyond reproductive units.

Oxytocin release has a number of socio-positive psychological effects, including increased social attention, social recognition, and social memory. Oxytocin also reduces social anxiety and stress. All these effects facilitate social interactions and, in turn, bond formation with conspecifics. Oxytocin receptors are found in reward centers in the brain, suggesting that this hormone reinforces affiliative interactions by facilitating their occurrence in the future.

Social experience during early development, such as attachment style with the mother, has important consequences for social bonding (reviewed in Crockford et al. 2014). For example,

in humans and macaques mothering styles are impaired, showing abusiveness or overprotection, if the mother experienced early separation during development, and in vervet monkeys mothering styles of mothers and daughters are correlated. In both human and nonhuman primates, individuals that experienced trauma during early development have impaired social functioning as adults. There is evidence that early social experience affects the development of oxytocin-related physiological mechanisms, pointing again on the pivotal role of this hormone in social bonding.

## Bond Maintenance

This complex proximate machinery regulates the formation and maintenance of social bonds by influencing behavior toward the partner. How social bonds are expressed in animal behavior often depends on the species, but it is generally recognized that mutual tolerance, reflected by a close spatial proximity, is a good indicator of bonds across animal taxa (reviewed in Dunbar and Shultz 2010). Maintaining close proximity with affiliated individuals allows monitoring their activities and therefore is crucial for various benefits associated with affiliative bonds, ranging from antipredator protection of the offspring to mutual support in agonistic interactions with conspecifics. Coordinating activities with the partner has also been recognized as an important component of a bonded relationship, especially in pair-bonding animals where coordinating activities with the partner is crucial for effective rearing of the offspring.

Although social bonds can be long lasting, they require constant re-evaluating or re-affirming to ensure their maintenance, with many animals exhibiting signaling behaviors that function specifically in this way. By duetting, for example, pair-bonding birds and other animals test each other's attention to the partner's actions and, in turn, the bond between them (e.g., Smith 1994). A similar function can be attributed to synchronous swimming or surfacing in dolphins or dancing in humans. In most primates, reciprocally balanced grooming seems to be the main bonding

behavior, which explains why this activity consumes considerably more time than required by its original hygienic function. By routinely producing these affiliative signals animals reinforce the bond between them, which in turn facilitates mutually beneficial forms of social support such as tolerance or aid in agonistic interactions.

## Bond Flexibility

Since maintaining social bonds is a costly process especially in terms of time devoted to it, their formation must be favored by specific conditions. Exploring factors mediating bond formation, especially in group-living species, is therefore an especially interesting research avenue. One study showed, for example, that in periods of social instability, female baboons limit their grooming interactions to a smaller number of individuals consisting of core social partners that are more likely to provide support (Wittig et al. 2008). This suggests that social bonds are not inflexible but swiftly adjusted to the current social situation. Since social bonds are often linked to within-group competition, it is likely that its degree, reflected by the intensity of agonistic interactions or dominance relationships, is another factor influencing patterns of social bonding with specific individuals. Investigating social factors affecting social bonds, therefore, has the potential to expose selection pressures driving their evolution in group-living animals.

While the adaptive importance of strong, long-term bonds in group-living species has been widely recognized, the role of more flexible, temporary affiliations should not be underestimated. Forming such short-term social bonds or coalitions with individuals that are not necessarily affiliated on a long-term basis might be particularly important in animals, such as chimpanzees or humans, where grouping patterns are often unpredictable due to animals forming temporary subgroups which size and composition frequently change. In such fission-fusion societies, preferred long-term social partners are not always available. Perhaps to cope with this challenge, male chimpanzees use flexible and time-efficient signals

such as chorusing to facilitate short-term coalitions with both long-term preferred and neutral social partners (Fedurek et al. 2013). Similarly, while it has been shown that strong social bonds in baboons bring about clear adaptive benefits, in some baboon populations the number of weak (i.e., temporary) rather than strong or long-term social relationships predict offspring survival and longevity (McFarland et al. 2017). It is possible that strong and weak social bonds complement each other (Fedurek et al. 2013) and that the relative importance or prevalence of these two types of bonds depends on specific social and ecological conditions characterizing a given population (McFarland et al. 2017) – a topic that should be explored in more detail by future studies.

[Age-related](#)

## Definition

An ordering pattern for animals or conditions that is based on age. Often the “value” of different age-grades is thought to increase with age, also referred to as age-positive or positive age-graded pattern. Or the value first increases and then decreases with age, referred to as inverted U-shaped or J-shaped pattern. The latter can turn into an age-inversed pattern, also called negative age-graded.

## Introduction

In its most general form, the term “age-graded” refers to an age pattern underlying a particular

condition or a change (i) in an organizational social characteristic; (ii) of an anatomical, physiological, or cognitive feature; or (iii) of a behavior or a behavioral syndrome. Specifically, in the social sciences, the term “age grade” is used to describe an organizational pattern in a society. In developmental biology and individual life histories, age-gradedness is common, because an organism undergoes predictable, age-related changes, for example in hormonal status. Such age-related changes also occur during cognitive and behavioral development.

In behavioral studies, the term is most commonly used in studies describing the patterns of dominance relationships and the structure of dominance hierarchies. Here, the way in which age relates to or affects dominance rank leads to several distinct patterns, which vary across species and sexes. Often these patterns can be explained through variation in fighting abilities over the lifetime of an individual. At the same time, additional variables need to be taken into account, such as presence of kin, resource value, coalitions, winner-loser effects, etc., to fully explain the emerging patterns.

### Age, Fighting Ability, and Rank

When animals compete over access to limited resources, such as food, mates, etc., the outcome of an interaction is often determined by the fighting abilities of the contestants also referred to as resource holding potential or resource holding power (RHP; Parker 1974). Based on repeated interactions with consistent outcome, a dominance rank (or rank for short) can be assigned to an individual relative to other individuals, either in a group or a population. Generally, assuming that all other things are equal, the fighting ability of an individual determines its rank (see also “basic rank”), and age-graded patterns of rank emerge depending on the relationship between RHP and age.

Initially, individual fighting ability increases with age, because size, strength, and weaponry

increase during ontogeny and maturation. After maturation, the further development of RHP varies across species (Clutton-Brock 2016). If an individual reaches its peak strength soon after maturation, the rank trajectory will be “J-shaped” (Fig. 1, RHP peak 1). More specifically, as individuals grow and mature they challenge older and weaker individuals, enter the hierarchy, and rise in rank. They reach their peak in rank when they reach their peak strength. Thereafter, they lose to younger and stronger individuals and drop in rank. The situation is similar in species, in which peak strength is reached later after maturation, but the increase in rank is slower and the trajectory resembles an “inverted U-shape” (Packer 1979; Fig. 1, RHP peak 2). Examples for these rank trajectories can be found among some male primates, red deer stags, and female horses. Notably, rank trajectories of individuals may depart from this pattern through coalitions or other factors affecting the relationship between age and RHP (Alberts et al. 2003).

In some invertebrates and vertebrates, individuals never cease to grow (called indeterminate growth), while in others, body mass (but not structural size) increases or weaponry continues to develop after maturity. If size, mass, or weaponry are decisive in competitive interactions, the average rank trajectory should follow the trajectory of RHP, that is, the youngest individuals should be at the bottom and the oldest individuals at the top of the hierarchy. This pattern is frequently referred to as age-graded, although the more precise term would be “age-positive” or “positive age-graded” (Fig. 1, RHP peak 3).

In the typical case, an individual matures in a group or a population or an individual immigrates into a new group. This individual, if it is the youngest with the lowest RHP, takes the lowest slot in the hierarchy. Over time new individuals cue at the bottom while older, higher ranking individuals die and the aging members of the cue become higher ranking. Positive age-graded patterns are common, for example, in ungulates and elephants as well as male hyenas, female dolphins, and a few female primates such as

**Age-Graded, Fig. 1** Average trajectories for dominance ranks following age-related changes in RHP under three conditions (RHP peak 1: shortly after maturation; RHP peak 2: several years after maturation; RHP peak 3: late in life) leading to J-shaped, inverted U-shaped, and age-

positive patterns. Under all three conditions, an individual occupies the highest ranks during the time it reaches its peak RHP. Other factors affecting rank play a negligible role

gorillas and chimpanzees (Clutton-Brock 2016). Clearly, such a system will not always be perfectly age-related. For example, the position at entry into a hierarchy is variable and can depend not only on an individual's fighting abilities but also on the presence of kin and other factors as has been documented for female chimpanzees (Foerster et al. 2016). Similarly, if individuals survive long enough they can become weak and senile such that the oldest individuals in a population or group drop in rank.

Importantly, while age-related trajectories can be driven by fighting abilities as outlined above, factors other than RHP can influence rank as well (see also "dependent rank"). Under such conditions, age-related trajectories can emerge, in which the peak rank does not coincide with peak RHP.

An extreme variation of J-shaped trajectories occurs in some female primates such as mantled howler monkeys, gray langurs, and Phayre's leaf monkeys (Lu et al. 2013), which exhibit "age-inversed" or "negative age-graded" hierarchies (Fig. 2). The key difference is here that individuals occupy the highest ranks that are not yet adult and clearly before their peak in RHP (Hrdy and Hrdy 1976). The emergence of this pattern is still

unexplained, but has been theoretically linked, among other things, to age-related changes in resource value (Broom et al. 2009).

In yet other cases, the rank trajectory follows an inverted U-shape; however, the highest ranks are occupied by individuals that are several years beyond peak RHP (Fig. 2). In the extreme case, old and weak individuals occupy the highest ranks (Fig. 2; age-positive). Because older but weaker individuals occupy the top ranks, these patterns indicate that factors other than RHP allow these individuals to outrank younger, stronger ones. One explanation for these two patterns is so-called winner-loser effects (Dugatkin 2014). Here, individuals entering a hierarchy are beaten by stronger (older) individuals. This initial win will increase the likelihood of winning in the future. Similarly, the initial loss will increase the likelihood of losing in the future. Over time the winner is more likely to win and the loser is more likely to lose, even if the RHPs of the contestants should reverse with time. This mechanism is a potential explanation for the age-positive nature of female chimpanzee hierarchies (Foerster et al. 2016). Another mechanism is the formation of coalitions by older individuals to outcompete younger and stronger individuals as has been

**Age-Graded, Fig. 2** Average trajectories for dominance ranks following age-inversed, inverted U-shaped, and age-positive patterns. All three trajectories are “independent” of the peak RHP. In an age-inversed pattern, individuals

occupy the highest ranks before peak RHP. In an inverted U-shape and an age-positive pattern they occupy the highest ranks after they reached peak RHP. For mechanisms maintaining these patterns see text

observed, for example, among Barbary macaque males (*Macaca sylvanus*). The extreme cases are some human societies such as the Samburu people. In their gerontocracy, the oldest members maintain their power through social values, ritual practices, and punishment (Spencer 2004).

- [Resource Holding Potential](#)
- [Resource Holding Power](#)

## Conclusion

The term “age-graded” is often indiscriminately applied to all kinds of age-related patterns. Often it is used to describe an “age-positive” pattern. But other patterns are possible, making it necessary to clearly describe the trajectory (age-inversed, J-shaped, inverted U-shape, age-positive) more precisely. These patterns are the result of changes in fighting ability over the lifetime of an individual, but additional factors can modify the relationships between age, RHP, and rank.

### Synonyms

[Individual-based modelling](#); [Individual-orientated modelling](#); [Multi-agent systems](#) (has other meanings, occasionally used as synonym.)

### Definition

Agent-based models are a type of model based on computer simulation, where the behavior of a system is determined by the activities of autonomous individuals and their interaction with and through an environment.

### Introduction

Agent-based modelling (ABM) is a research method for understanding the collective effects of individual action selection. More generally, ABM allows the examination of macrolevel effects from microlevel behavior. Science requires understanding how an observed characteristic of a system (e.g., a solid) can be accounted for by its components (e.g., molecules). In ABM, we build models of both the components and the environment in which they exist, and then observe whether the over-all system-level behavior of the model matches that of the target (or *subject*) system. Constructing agent-based models (ABMs) can be seen as a form of theory building. The consequence of expressing a theory as a simulation is that many aspects of the coherence and explanatory power of the theory can be checked by examining the simulation outputs.

Typical elements of an agent-based model are the attributes and behaviors of agents, the

relationships between agents and their interactions, the environment, and how the agents interact with and through the environment (Macal and North 2010).

ABM is still a sufficiently new research methodology that there is still some controversy in its use, and still some unevenness in its application and description in scientific papers. ABMs can be very sensitive to initial conditions and can produce complex behavior which can be difficult and computationally intensive to analyze and understand. Without sufficiently established methodological practice, it can sometimes be difficult to incorporate ABM results into true scientific discourse. However, the practice is becoming more widespread and ABMs are frequently included as one form of evidence in many high-profile scientific articles.

In this article, we review ABM and the techniques for its analysis. In the section “[History](#),” we discuss the history of ABM and give some examples of where it has been used. In the section “[Designing and Running ABMs](#),” we discuss the considerations to be taken into account when designing and running ABMs, and popular platforms for constructing them. In the section “[Analyzing ABMs](#),” we discuss the analysis of ABMs and how this can be used in theory building. Finally in the section “[Example: Flocking Behavior](#)” a simple and well-known ABM is described – that of the flocking behavior of birds by Reynolds (1987).

### History

Agent-based models emerged from work on cellular automata (CA), the first of which was created by John von Neumann and Stanislaw Ulam in the 1940s. Their idea was to try to build a machine that could autonomously reproduce itself, and the solution was a complicated set of rules on a grid. In 1970, John Conway simplified this idea in his Game of Life (1970). This game involves a grid of cells in which every cell interacts with its eight neighboring cells according to four basic rules which decide whether the cell will live or die. These basic rules create many different emergent

and complex patterns including one which copies itself in the process of destroying itself.

In the 1970s, one of the first ABMs was developed. This model was developed by Schelling and was used to study segregation (Schelling 1971). This model was implemented by physically placing dimes and pennies on a piece of graph paper, where a coin moves location if it has a majority of immediate neighbors of the other coin type. After a number of these moves, the emergence of segregation of pennies and dimes can be seen. Thus, in this model agents (the coins) make decisions and interact with one another in an environment (the grid) – contrasting with CA models where it is only the environment that is considered.

After Schelling's physical implementation of an agent-based model, ABMs began to be programmed using computers. This meant they could be more complicated and run for many more iterations. Thus, ABM became a more useful tool and work using them truly began. Robert Axelrod was a key player in the first work using computer based agent-based models. Axelrod's early work focused on using ABM to study the best solutions to the iterated prisoner's dilemma – a game theoretical model of cooperative behaviors (Axelrod 1984). Axelrod remains one of the area's main advocates.

Other early applications of ABM were in biology. Hamilton (1971) and Hogeweg and Hesper (1979) used early modelling techniques to establish basic principles of animal sociality. In the 1980s, ABMs also started to be used to study specific animal behaviors, such as the social interaction structure and ontogeny of bumble bees (Hogeweg and Hesper 1983) and the flocking behavior of birds (Reynolds 1987). After these initial developments and progressively powerful computational power, ABMs have become an increasingly popular tool in animal behavior, ecology, the social sciences, the life sciences, and economics.

A notably large early agent-based model was the simulation of whole artificial societies in the Sugarscape model by Epstein and Axtell (1996). This model looks at a simple grid environment where sugar is distributed unevenly and agents move from cell to cell and use the sugar as a

resource (whether it be for food or a trading material). By adding more rules, the model can be interpreted to show complex social behavior including disease transmission, inheritance, trade networks, economic inequality, and combat.

Research using ABMs has also included how culture changes and spreads (Axelrod 1997a), the evolution of cooperation (Axelrod 1997b), the societal collapse of the Anasazi people (Dean et al. 2000), social behavior in primates (Hemelrijk 2000), the study of agricultural economics (Berger 2001), the spread of cancer (Preziosi 2003), land use (Brown et al. 2005), predator-prey relationships between killer whales and other marine mammals (Mock and Testa 2007), sharing information (Čače and Bryson 2007), crowd behavior during emergency evacuation (Pan et al. 2007), and the adaptive immune system (Folcik et al. 2007). They have become an established method used broadly in high-impact publications in the social and biological sciences, including studies of political party policy dynamics in Ireland (Laver 2005), schisms in religion (Whitehouse et al. 2012), the impact of naive individuals on consensus formation (Couzin et al. 2011), the appearance of modern human behavior (Powell et al. 2009), and the origins of war (Choi and Bowles 2007).

Agent-based models can therefore now be accepted as widely used. They are able to demonstrate interesting, unexpected, and complex behaviors even from very basic rules, sometimes of extreme scientific importance. However, without properly analyzing and validating the results found from an agent-based model, the work can be as ungrounded as a computer game, rather than demonstrating real scientific progress. We address this issue in the section “[Analyzing ABMs](#).”

## Designing and Running ABMs

Designing a model involves knowledge and assumptions about the system being modelled. Models are abstractions of reality, and therefore they do not have to contain every single factor to do with the system. Because of this, decisions on which important components to include in the

**Agent-Based Modelling, Fig. 1** A flow diagram of key steps in the modelling process. It is important to note that the observed data which are used to inform on the model’s design should not also be used in the model-validation step

model, and those which do not need to be included, need to be made. These decisions can be based on which dynamics are of particular interest, the aspects of the system for which data are available, and more subjective or literature-based decisions about which factors are believed to be theoretically important.

There are several platforms for implementing agent-based models, including NetLogo (Wilensky 1999), Repast (North et al. 2013), MASON, and Swarm. A comparison of these is given by Railsback et al. (2006). However, the use of a platform is not mandatory and an agent-based model can be coded relatively easily in an ordinary programming language, particularly languages that are object oriented. However, many platforms provide tools for visualization and analysis that model authors find useful.

Often there will be stochastic elements to ABMs. Due to this, every time a model is run the results will be somewhat different, just as in many experiments with the physical world or living animals. In these cases, models should be run multiple times in order to know that the results found are representative. By running the ABM many times the user can get an idea for how variable the results are, and what kind of general model results occur. If the results of different runs of the model vary more largely than is predicted by theory, it could be a sign that the model has not been implemented properly and there may be a bug in the code, or equally that the theory is incorrect. Determining which is the problem is also a matter of analysis.

After designing, building, and running the model, it should then be verified and validated.

These will be discussed in the next section. Key steps in the modelling process are shown in Fig. 1.

### Analyzing ABMs

After running an ABM, the next step is to analyze the resulting outcomes. Analyzing results is done by observing what happens in the model after a certain number of iterations, or over a number of runs. Different experimental runs may use either the same parameters, in order to discover the range of possible results due only to the effects of random variation; or use systematically varying parameter values, to test the significance of each parameter set or *condition* (parameter sensitivity analysis). In-depth analysis of these observations can aid in understanding how the ABM is working and how sensitive it may be to different parameter values.

In order for ABM (or any model) to be useful to science, it must provide both a means of explanation and a mechanism for improving that explanation. The explanatory force of the model is the extent to which an observed meta-level phenomena can be accounted for by the behavior of its microlevel actors (Bryson et al. 2007). Thus, in model validation, the explanatory force of the model is analyzed. Models that do not perfectly match real-world data can be improved by postulating additional characteristics of the model; those that do meet requirements may possibly be improved or made more general by simplification – that is by discovering whether any aspects of the model are not necessary to the outcome and can be removed.

### Parameter Sensitivity Analysis

Sensitivity analysis is used to investigate how input parameters affect the outcomes of the model. If there is uncertainty in the value for the input parameters, then this analysis will give some idea of the degree to which this impacts the results from the model. Unless a particular range of parameter values is specified in the theory behind the model, over-dependence on specific values can be seen as fragility in the model, though they may also serve as a prediction coming from the model concerning what values the parameter correlates may be expected to hold in the target system the model describes.

A commonly used type of parameter sensitivity analysis is investigating the effect of varying one parameter while keeping all the others at their default values (the “fix-all-but-one” method). With increasing model complexity, the effects parameters have on the outcomes of a model can become exponentially more difficult to analyze. Varying one parameter at a time reduces this complexity, but relies on having a default value to set the other parameters to. Where such values are not known, e.g., when there are insufficient data available, an ill-considered default value may be chosen and an important range of model outcomes overlooked. However, if there are data which suggest that only a small range of values are realistic, then the complexity of the search may be reduced even where no exact value is known.

A more thorough type of parameter sensitivity analysis is to vary all parameters randomly within a predefined range of realistic values. By doing this for many runs of the model, the parameter set space can be investigated more comprehensively, and there is less chance of overlooking important model outcomes because of ill-defined default parameter values. However, since this approach investigates multiple parameter changes at the same time, the results are more challenging to analyze than those using the fix-all-but-one approach. Cluster analysis can be used to distinguish the types of model output that occur when

the model is run many times with random parameters, and then the parameter value distributions for each cluster can be determined (Gallagher 2017, p. 162).

### Model Verification and Validation

As ABM has become more prevalent, there has been an increasing emphasis on developing methods of verification and validation (Balci 1998; Kennedy et al. 2005). *Verification* is the process of making certain a model runs as designed. In science, this is roughly equivalent to ensuring that good experimental practice has been followed. This can be done by debugging and peer-reviewing the code to make sure that all components of the system act as expected. *Validation* is the process of making certain the model actually models the target system. When ABMs are used for sciences such as biology, validation is equivalent to hypothesis testing (Bryson et al. 2007). Model validation may be seen as one mechanism of model verification, provided that successfully replicating the behavior of the target system is unlikely to occur by chance.

There are only two important criteria for validating an ABM. These are the same as for validating any behavioral model:

1. Does the behavior of the ABM match the behavior of the target system within the standard metrics of hypothesis evaluation?
2. Do all the attributes of the agents and their environment have plausible correlates in the target system being modelled?

Regarding the “standard metrics,” these depend largely on the success of previous explanatory efforts. If the literature contains no prior explanation or model, then it may be sufficient to show a qualitative similarity between the model and the target system. The model is now a theory explaining the data, and as the first one it is necessarily the best. However, if there is another competing model, then we need either to use standard statistical

hypothesis testing to decide which will be the better match, or possibly to argue one model is more parsimonious, though such arguments can be problematic (Myung et al. 2000). For the second criterion, the issue is whether the modeler has given the artificial agents any capacities that real subjects could not or arguably would not possess.

There is a common perception that ABMs are so complex (i.e., have so many parameters) that they can be made to easily match any data or predict any outcome, but that having done so the system will have no capacity for generalization and therefore no predictive power. In practice, however, building and debugging ABMs is a difficult skill, and matching datasets is not easy. While it is true that ultimately most datasets can be matched, the principle value of the model is expressing what aspects need to be changed in order to generate these various outcomes. Again, a working model is best understood as a theory of the system, and any parameters and parameter values required for that model to work that were not a part of the original theory are predictions derived from that theory.

If a model is built first to a set of justified assumptions and *subsequently* matches a dataset with minimal adjustment, then it can be considered to be at least partially validated. Of course, the more datasets it matches, the better-validated the model becomes. As this notion of *better-validated* implies, validation is not simply a state that either holds or does not hold for a model. Rather a model, like any scientific hypothesis, becomes more *probable* (given the data) the more it is validated. But a model never becomes perfectly certain (Box 1979). Indeed, the purpose of any theory is to abstract from the real world and that process of abstraction necessarily entails losing detail and precision. The only exception is if a model becomes understood to such an extent that it can be *proven* correct in a logical or formal analytic sense.

This observation returns us to the matter of verification. Verification is most pernicious in purely formal systems, where validation cannot

be grounded in real-world data. A proof can only be judged by human reasoning and is only as good as its premises (Bundy et al. 2005; Edmonds and Bryson 2004). Formal systems are used in mathematics and similar disciplines as a mechanism of knowledge *discovery*, and therefore, verification is both more critical and more difficult. Again, when validation is performed via hypothesis testing against real-world data, validation itself serves as a form of verification. To the extent a computational model reliably matches and predicts a target system's performance, then it *is* a model, in the formal sense of the word.

### ABMs as Scientific Hypotheses

The scientific method is a process of “systematic observation and experimentation, inductive and deductive reasoning, and the formation and testing of hypotheses and theories” (Andersen and Hepburn 2016). In this way, hypotheses can be continuously improved by refinement or rejection. As stated above, ABMs may be viewed as a scientific theory about how the real-life system behaves, and as such model validation is a form of hypothesis testing (Bryson et al. 2007). Hence, every time we validate a model, we can learn something new about how the real-life system might work and then refine hypotheses about this system accordingly. Thus, in the next version of modelling a particular system we may have even more robust ideas about parameter values or relationships within the model and its target system.

The analysis of an existing agent-based model can be done as a three-phase process (Bryson et al. 2007). The first phase is a *replication* of the model. This may not seem (or even be) strictly necessary in the case where the model is publicly available – the results in that case can be checked just by rerunning the original model on another computer. However, reimplementing the model from its description in the literature can be a valuable exercise. Reimplementation may uncover important aspects of the model that the model's original authors either took for granted,

overlooked, or even forgot about during the course of their research (King 1995; Axtell et al. 1996). ABMs may be valid without actually having been fully verified or understood. This is true of any scientific hypothesis; part of the scientific method is improving this understanding of a theory as a community.

Once the critical attributes of the model are well understood, we can enter the second phase of the analysis, *model understanding*. Here, we carefully consider what the implied or the explicit correlates of those attributes are. Again, just as in any science, we go through a process of finding testable predictions and implications that result from our hypothesis. The third and final phase is *testing* these predictions and implications, looking first into the extant literature, and then (if necessary) to proposing and executing new experiments or measures on the target system.

With regard to the second phase, two similar methods can be used to predict what parameter values in the model give the most realistic results and thus help us to make inferences about the real-life system. These methods are fitting to idealized outcomes (FIO) (Gallagher et al. 2015) and approximate Bayesian computation (ABC) (Beaumont 2010). Both approaches have three steps:

1. The model is run many times with random parameter values.
2. Observed data, whether rich in detail (in the case of ABC) or imprecise (in the case of FIO), are compared to every run of the model. Model runs that give the closest match to the observed data are then separated out.
3. The parameter value combinations which were used in these closest-match model runs are interpreted as potentially being most realistic. Where the model includes stochastic elements, it is wise to check that the fit holds for repeated runs.

As mentioned in the section “[Parameter Sensitivity Analysis](#),” step 1 allows trends between the parameters and the outcomes to be seen, as well

as studying parameter interdependencies and sensitivity.

Step 2 is where ABC and FIO differ. In ABC summary statistic(s) from observed data are compared to the same summary statistic(s) from the modeled data. Thus, in ABC the comparison of the simulation and observed data is much more robust, and thus ABC can be used to validate complex models. However, to do this ABC relies on having detailed observed data, which is not always possible. Thus, if observed data are not rich enough to allow ABC, but some general outcome either is known or is of interest, FIO can still be used in model validation.

In step 3 the two methods allow a prediction of what parameter values are likely to cause observed data and which parameter values are not. And thus using these methods we can make new and informed predictions about the real-life system, which should then be tested in the third phase of analysis.

## Example: Flocking Behavior

A popular and early example of ABM is the model of coordinated animal movement posited by Craig Reynolds (1987). This model, called Boids, has proven extremely fertile in biology (Couzin et al. 2011; Hemelrijk 2000).

The Boids model has three basic rules which determine how each agent (or “boid”) moves:

1. Separation: if another agent is too close, then steer to avoid it.
2. Alignment: calculate the average direction of the surrounding agents and steer to move in this same direction.
3. Cohesion: steer to move toward the average position of nearby agents (but do not get too close).

Depending on various parameter values chosen in this model (e.g., the minimum distance apart and the maximum distance an agent can observe around itself) and how long the model is run, different macrolevel behavior can

A

**Agent-Based Modelling, Fig. 2** Positions of agents in the Boid agent-based model by Reynolds (1987). Implemented in the “Flocking” model example in NetLogo 5.1.0 (Wilensky 1999). (a) shows the starting positions of agents, (b) shows the positions of agents after 100 iterations

of the model when agents can see moderately far around them, and (c) shows the positions of agents after 100 iterations of the model when agents can see very far around them

emerge. For example, if the agents can be quite close together and see moderately far around them then here might be multiple flocks of agents, but if they can see very far around them then a single flock of agents can emerge. Examples of these flocking behaviors can be seen in Fig. 2.

The initial locations and directions of agents are randomly chosen every time the model is run, and thus even with the same parameters each run of the model can look very different.

As an entirely fictitious example for purpose of illustrating the process of making predictions from this model, let's assume that the average number of birds in a real-life flock is 20, for some species and set of circumstances. We can run the model many times while varying the parameter which accounts for how far around it each agent can observe other agents. Every time the model is run, we record the mean number of agents in each flock. By selecting the runs of the model which gave average flock sizes of 20, we can then find which parameter value was used in these runs. Thus, from this we can make a prediction of the distance birds can observe the direction of travel and positions of other birds.

A real-world example of an analysis of a very similar model to boids posited to explain primate social hierarchies is presented by Bryson et al. (2007).

## Conclusion

Since the 1980s, agent-based modeling has become an increasingly popular tool in animal behavior studies, social sciences, economics, and life sciences. ABM focuses on modelling the microlevel behaviors of the system and examining the macrolevel effects these can have. To be useful to theory building, ABMs need to be validated by comparison to the real-life system which is being modelled. In this way, new insights, sharper intuitions, and predictions can be made.

## Definition

An aggregation refers to both the process of grouping and the resulting spatial gathering of animals.

## Introduction

Animal aggregations are the most basic form of social life, on top of which more elaborated social behaviors, such as cooperation and division of labor, have evolved. Aggregations are observed across the animal kingdom, from insects all the way to humans. Depending on the developmental stages of animals and the environmental conditions, aggregations can take various forms. They can count just a few individuals or several millions, involve physical contacts or only spatial proximity, be spatially stable or move, and last a few seconds or persist for a long time. Additionally, aggregations can have a stable composition or show a regular turnover of individuals.

## Passive Versus Active Aggregations

Two broad types of aggregations are generally considered (Parrish and Edelstein-Keshet 1999). Passive aggregations refer to groups that develop in response to environmental heterogeneities (e.g., shelters, light, food sources, marine

currents, or wind), while active aggregations result from inter-individual attraction (e.g., social interactions). In this case, group formation is mediated by social stimuli that are actively emitted (signals), for instance, when animals need to recruit others to a target (e.g., pheromones), or passively displayed cues (e.g., footprints). While passive aggregations always develop around environmental heterogeneities, active aggregations can also be observed in homogeneous environments (e.g., empty arena).

## Mechanisms of Grouping

The mechanisms of group formation and disruption have been extensively studied since the 1980s, with the development of self-organization theory and experimental approaches combining behavioral observations, simulations of

computational models, and implementation in autonomous robots (Camazine et al. 2003).

## Group Formation

Aggregations develop based on feedback loops that influence an individual's tendency to join others and stay grouped in response to aggregation stimuli (e.g., Lihoreau et al. 2016). Long-range stimuli (e.g., volatile pheromones or visual displays) often have an attractive effect, whereas short-range stimuli (e.g., nonvolatile pheromones or contacts) tend to be retentive. These attractive and retentive effects can be additive, for example, in active aggregations of blowfly larvae where the larger the group the higher the probability that individuals join and stay (Fig. 1).

## Collective Movements

Once an active aggregation is formed, various patterns of collective motion can emerge from

**Aggregation, Fig. 1** Mechanisms of group formation and fitness consequences in necrophagous blowfly larvae (Diptera: Calliphoridae). Positive feedbacks are represented by orange arrows. Negative feedbacks are represented in red. Larvae leave a chemical trail as they move on the substrate. These cuticular cues, along with thigmotaxis, maintain larvae densely aggregated, which results in deep modifications of the environment. First, the metabolic heat emitted by larvae increases temperature up

to 45 °C in large maggot-masses. Second, the exodigestive enzymes and the mechanical action of the hundreds of mouth-hooks break muscular fibers and liquefy flesh, while highly efficient antimicrobial compounds control the growth of yeast, fungi, and bacteria. The combination of these effects favors the fast development of larvae (Allee effect). In case of overcrowding (e.g., food depletion or overheating), larvae move to the periphery, resulting in a self-regulation of the aggregation

attraction, repulsion, and alignment forces between individuals (Couzin et al. 2005). Animals can collectively rotate around an empty core (e.g., schooling fishes), dig the food substrate (e.g., drosophila larvae), or migrate to a new favorable environment (e.g., marching locusts). A general feature of these collective movements is their density-dependence. During population outbreaks of desert locusts, nymphs form marching bands that can extend over kilometers. When high densities of nymphs are reached, individuals start to align their displacements, reduce collective changes in direction, and ultimately move together in the same direction (Buhl et al. 2006).

### Group Disruption

In most cases groups erode from the independent leaving events of individuals (e.g., animals on a food source become satiated and leave). However, quick synchronized dispersion can also result from social interactions, for instance, in response to a stressing event (e.g., predators). In fruit fly aggregations, the number of immobile individuals has an inhibitory effect on the probability of leaving. But following exposure to an aversive odor (e.g., CO<sub>2</sub>), contacts between moving individuals that start fleeing and stationary individuals that did not yet respond to danger trigger collective escape behaviors (Ramdya et al. 2015).

### Costs and Benefits of Grouping

Aggregations provide a range of fitness benefits to individuals that typically increase with population density and peak at a critical density. This pattern is known as the “Allee effect.”

### Predation Risks

Aggregations can reduce predation risks through several mechanisms (Krause and Ruxton 2002). At the most basic level, for any one predator attack, the larger the group of prey animals, the lower the chance that any particular individual will be the victim (i.e., dilution effect). Grouping can also augment the efficiency of vigilance

behaviors through information transfer (i.e., many-eyes effect) or distract predators that have more difficulties to focus and catch any single prey (i.e., confusion effect). In conditions of overcrowding, however, aggregations may attract more predators and parasitoids, as well as favor the spreading of diseases and pathogens among group members.

### Modifications of Local Conditions

The group itself can have an effect on local conditions and help individuals to cope with natural variations of the environment. Some animals protect themselves from cold by rising temperature above ambient. For moving aggregations, grouping can also reduce energetic expenditure during flight or swim, a benefit resulting from particular group structures (e.g., V formation in birds) that improve the aero- or hydrodynamism of individuals (Weimerskirch et al. 2001). Other animals, such as necrophagous blowfly larvae, modify their food resource by releasing metabolic heat and accumulating exodigestive enzymes that speed up food liquefaction and create favorable conditions for larval development (Fig. 1). At high densities, however, these group effects can become deleterious, leading to self-pollution (e.g., waste accumulation) or thermic stress.

### Information Transfer

Grouping may enables individuals to obtain important information about the environment that would otherwise be costly to acquire (Sumpter 2010). In active aggregations, information transfer can lead to collective decision-making whereby individuals agree on an option to take among other alternatives (e.g., a food source, a shelter, a direction). When some individuals detect a suitable option, their change of behavior is perceived by the others that tend to follow their choice. The probability of an individual to follow can depend on a quorum, i.e., a threshold in the number of individuals displaying the behavior. Through this process, large groups have lower probabilities to reproduce “mistakes” (i.e., non-adaptive behaviors) expressed by a single or few individuals. Such collective responses

often improve the speed and accuracy of decision-making.

## Mixed Species Aggregations

Although less studied, several animals form inter-specific aggregations (Boulay et al. 2017). This is the case in birds, where “follower” species can join “leader” species. In such mixed-species flocks, followers can benefit from the anti-predator vigilance of leaders, and thus re-allocate their energy to foraging. If resources are sufficiently abundant for limiting interspecific competition, benefits can be equally distributed between species (e.g., dolphins, seabirds, and sharks aggregating to concentrate large amount of preys), suggesting that the benefits of grouping can also drive the evolution of mutualistic associations.

## Conclusion

The benefits of aggregations, their emergent patterns, and their ubiquity among animal species have made them the subject of numerous studies in past and recent decades. While most research has focused on describing the general mechanisms leading to group formation and maintenance across a wide diversity of species, still little is known about the evolutionary processes that drive gregarious behaviors. Future developments in comparative quantitative research and evolutionary modeling are promising avenues to fill this gap.

## Definition

Conspecific aggression is an offensive behavioral strategy directed towards a competing member of the same species that is adapted to secure some resource at minimal cost.

## Introduction

Aggression, from the Latin *aggressio* for attack, is frequently used synonymously for agonistic behavior which include threats, displays, retreats, placation, and conciliation. Psychologists define aggression as a behavior intended to harm another individual, which is less fitting for animals as they need not act with intent. Furthermore, while aggression is symptomatic for numerous psychiatric disorders, it is not necessarily an aberrant behavior, and it is considered to be adaptive for evolution and survival of animals and humans alike. Even so, there are still differing schools of thought on the origin and cause of human aggression (Bushman and O'Brien 2017). This contribution, however, summarizes insights into mechanisms controlling aggression in animals – specifically that between animals of the same species (conspecific aggression, as opposed to interspecific aggression, e.g., between predator and prey). A main focus is on cognitive processes. Traditionally, cognition basically refers to the capacity of the human mind to control what it does (Domingo, this volume). In animals, it encompasses the neuronal processes of perception, learning, memory, and decision-making that enable animals to perceive, process, and retain information about the world and decide to act on it (Rößler and Auersperg, this volume). Put simply, this article outlines how animals make the decision to fight or flee in agonistic encounters with conspecific rivals.

## Conspecific Aggression in Animals

Conspecific aggression is known in members of all major animal groups, from simple sea anemones to the great apes. Darwin recognized that this widespread occurrence reflects the fact that the

“struggle for existence” is “most severe between the individuals of the same species, for they frequent the same districts, require the same food, and are exposed to the same dangers.” Animal aggression hence serves primarily to obtain or defend some resource. Their contests typically follow a stereotyped sequence of behaviors, starting with threats and escalating to physical engagement with use of “weapons” (mandibles, horns, teeth, claws) that can inflict injury and even kill. Even so, animals tend to fight with “gloved fists” and resolve disputes before serious injuries occur. This seemingly selfless or altruistic behavior was once thought to have a “species preserving” function. Later, application of Game Theory to contests between hypothetical animals with different fighting strategies (Maynard Smith and Price 1973) led to the recognition that restrained aggression is an Evolutionary Stable Strategy that maximizes individual fitness by avoiding costs of self-injury (see Dawkins 1976 on Kin Selection and Selfish Gene Concept, as opposed to Group Selection). Conspecific aggression can therefore be defined as an offensive behavioral strategy directed towards a competing member of the same species that is adapted to secure some resource at minimal cost. Animals must, therefore, perform a cost-benefit analysis in order to decide when best to fight or flee. To do this, they are thought to assess information from agonistic signals exchanged during fighting to determine individual Resource Holding Potential (RHP), or put simply win chances (see, e.g., Arnott and Elwood 2009). An individual’s RHP depends largely on physical factors (size, strength, weaponry, energy reserves), but also on aggressive motivation, i.e., the tendency to invest energy in fighting. Fight motivation is mostly promoted by the presence and value of resources, previous wins, and physical exertion, but suppressed mainly by previous defeats. But what are the underlying proximal mechanisms? How is aggressive motivation represented in the animal brain, how do experiences influence it? How is information gained from agonistic signals used for assessing win chances? Just how do animals appear to know when best to fight or flee?

## Neural Control of Aggression

The neural circuits controlling aggression in mammals are embedded within the “social behavior network” that regulates other social behaviors and are dauntingly complex (Nelson and Trainor 2007). Functionality in neuronal circuits is determined to a great extent by chemical messengers released from the synapses that connect the neurons and include locally acting neurotransmitters and neuromodulators with wider spread actions that can bias the output of entire circuits. Neurochemicals controlling aggression (de Boer and Koolhaas 2017) have been identified by measuring behaviorally correlated changes in their levels, and from the effect of selective drugs (receptor agonists and antagonists, inhibitors of transmitter synthesis, release, degradation, and re-uptake), and genetic engineering (“knock out” or disruption of genes controlling synthesis and functioning of transmitters and their receptors). They include the amine neuromodulators serotonin (5-hydroxytryptamine: 5HT), dopamine (DA), adrenaline (AD), noradrenaline (NA also termed norepinephrine), octopamine (OA, the invertebrate analogue of NA), the inhibitory amino acid neurotransmitter  $\gamma$ -aminobutyric acid (GABA), neuromodulator peptides such as vasopressin and oxytocin and androgens like testosterone. Their functions in aggression vary depending on their release site in the brain, and the receptor type activated. Manipulating these messenger systems have even more varied effects that depend on the age, sex, and social status of the animal, and its previous experiences and momentary mental state or specific behavioral context. Despite a wealth of information on their actions, insights into the natural behavioral functions of neurotransmitters in controlling the decision to fight or flee are only just beginning to emerge.

## Controlling the Decision to Fight

**Initiation:** Attack is typically initiated by specific releasing stimuli (web vibration in spiders,

red plumage in robins, male song in female crickets, male scent in lobsters and mice). In mammals, selected regions of the social behavioral network (ventromedial hypothalamus) elicit attack (Falkner et al. 2016). Multiple transmitters participate (Nelson and Trainor 2007; de Boer and Koolhaas 2017). AD/NA are generally accredited with preparing the animal to fight or flee, while brain NA facilitates aggression, but consistent relationships have not been found. DA, in the mesocorticolimbic system, also seems required for aggression, but its precise role is unclear. Testosterone promotes aggression, and lowering testosterone production by castration reduces aggressiveness in males. Oxytocin and vasopressin, which are released into the blood to regulate parturition and lactation, respectively, salt and water balance, are also released into the brain’s social behavior network. In rodents, vasopressin facilitates offensive aggression, as does its homologue arginine vasotocin in fish, whereas oxytocin generally has antiaggressive effects (Caldwell 2017). In crustaceans, 5HT induces the animals to adopt an aggressive posture and engage in fighting (see Huber 2005), whereas in insects OA promotes fighting behavior (reviews: Stevenson and Rillich 2016, on crickets; Hoopfer 2016; Asahina 2017, on fruit flies). In male crickets, antennal contact to another male is the natural aggression releasing stimulus and has both a mechanical and male-specific pheromone component. Although male antennal contact elevates OA levels, OA is not actually necessary for initiating aggression (Rillich and Stevenson 2015). In fruit flies, a male aggression-promoting contact pheromone has been identified along with responsive gustatory receptors that connect to OA neurons (Andrews et al. 2014), which then relay to recently identified neurons that control aggression (Watanabe et al. 2017). It seems that specific male and female pheromones act on different subsets of neurons that release OA as a neuromodulator to control the decision to fight contacted males, but court females. Furthermore, the presence of females elevates male-

male aggression, but not if the males had previous female contact. Apparently female pheromone inhibits aggression via the action of GABA (Yuan et al. 2014).

**Experience dependent promotion of escalation and persistence:** In mammals, many experiences influence neurotransmitter systems with consequences for aggression. Physical exertion can promote or suppress it, whereas resources and winning an encounter increases subsequent aggressiveness and win chances (Hsu et al. 2006). In humans, winners at sport have elevated levels of the androgen testosterone compared to losers. In fish the winner effect is actually mediated by androgens, and mice winners show an increased expression of androgen receptors (Oliveira et al. 2009; Fuxjager et al. 2010). In crickets, male antennal contact, the physical exertion of flying, and the act of fighting all lead to elevated levels of OA (Adamo et al. 1995). Furthermore, each of these experiences, as well as resource possession (residency in a shelter), increases a cricket's tendency to escalate and persist in fighting specifically via the action of OA (Stevenson and Rillich 2016). The neuromodulator OA thus represents the motivational component of aggression in insects by acting at numerous levels to increase the tendency to start and persist at fighting.

### Controlling the Decision to Flee

It is generally accepted that agonistic signals (threat displays and calls, physical force) exchanged during fighting serve as cues to assess win chances (or RHP) for the decision to fight or flee (see Arnott and Elwood 2009). Theoretically, this decision could be based on average differences in signal quality (Sequential Assessment Model), the sum of own actions (Energetic War of Attrition Model), or the sum of opponent actions (Cumulative Assessment Model), but there are few examples where the strategy is known. First insights into the basic underlying mechanism are known for crickets. Manipulating agonistic signaling and perception revealed that

crickets conform to the Cumulative Assessment Model in that they stop fighting and flee when the accumulated sum of their adversary's agonistic actions surpasses a threshold, which varies with aggressive motivation (Rillich et al. 2007). Put simply, crickets enter a fight prepared to receive a set amount of aversive stimuli (threats and knocks) and flee when the limit is reached. Later experiments revealed that the impact of the opponent's agonistic signals activates the NO signaling pathway which then induces retreat. Blocking this pathway causes crickets to persist exceptionally long, while activation causes them to give up earlier (Stevenson and Rillich 2015). Similarly, in male mice, genetic deletion of the enzyme for NO synthesis induces persistent fighting. This effect seems to result from influences on testosterone and 5HT signaling (Bedrosian and Nelson 2014). In mammals, 5HT is known mainly for its suppressing effect on aggression, although it also has promoting effects and complex interactions with arginine vasopressin (review: Morrison and Melloni 2014). The role of 5HT in insect aggression is presently unclear. As in mammals, 5HT can promote or suppress aggression in insects depending on the receptor subtype activated (Johnson et al. 2009).

### The Loser Effect

Losing an aggressive contest against a conspecific (social defeat) is followed by a period of reduced aggressiveness in most animals that can last for hours or days (Hsu et al. 2006). This loser effect is accompanied by changes in transmitter systems, but their role in loser depression is unclear (de Boer et al. 2016). In mice, approach or avoidance decisions after social defeat are biased by the 5-HT system under the control of GABA-releasing neurons in the dorsal raphe nucleus. Silencing these neurons prevents the acquisition of social avoidance in response to social threat (Challis et al. 2013). In crickets, the loser effect results from activation of the NO-signaling pathway at defeat (Stevenson and Rillich 2015) and can also be induced in crickets by applying an

aggression priming stimulus (antennal stimulation with another male's antenna) followed by a potentially aversive stimulus (wind stimulation of the cerci). As for the decision to flee, this context-dependent effect of aversive stimulation requires NO (Rillich and Stevenson 2017). Physical exertion (flying) and resource possession can each induce recovery of aggression after defeat via the action of OA (review Stevenson and Rillich 2016). However, DA but not OA is necessary for natural spontaneous recovery. In these territorial animals, recovery from social defeat is responsible for increased aggressiveness after social isolation (Stevenson and Rillich 2013).

### Chronic Social Defeat Stress

In mammals, social defeat is a major stressor that induces depression like symptoms that become severe following multiple defeats (chronic social defeat, Hammels et al. 2015; Yu et al. 2016). While 5HT plays some role, it is unclear whether it does so normally, or only under extreme pathological conditions (Olivier 2015). Chronic social defeat also induces long-term depression of aggression in fruit flies and crickets (Trannoy and Kravitz 2017; Rose et al. 2017) with possible lifelong consequences for future behavior. Aggression may thus determine behavioral differences between conspecifics (animal "personality" Briffa and Sneddon 2016).

### Genes and Aggression

Individual difference in behavior results from both the genetic background (nature) and social experience (nurture), but in varying degrees depending on the trait (Polderman et al. 2015). The impact of genes on aggression is evidenced by animals bred for hyper-aggressiveness, but the relationship is complex and poorly understood. Although individual genes affecting aggression have been identified in mice and fruit flies (Anholt and Mackay 2012; Hoopfer 2016), large numbers of pleiotropic and epistatically

interacting genes are associated with this complex behavior (Zwarts et al. 2012).

### Conclusions

The neurochemical systems involved in controlling aggression and the influences of various experiences on its expression are similar in many respects in widely different animals and imply a common evolutionary root. Indeed, some of the molecular mechanisms underlying this complex behavior in fruit flies show remarkable similarities to those in mice and even humans (Thomas et al. 2015). Even so, the complex social structures of "higher" animals call for a more flexible and precise control of aggressive behavior and associated emotions. "Lower" animals, such as invertebrates, have not only simpler nervous systems, they lack beyond reasonable doubt the complexity of emotions (fear, anger) and rely on instinct rather than rational for their decisions, which is a clear investigational advantage. Their social interactions, particularly in insects, are nonetheless intricate and flexible. Despite this, the seemingly complex cognitive task of deciding when best to fight or flee can be controlled reasonably simply, using neuromodulators to differentially adjust behavioral thresholds. So perhaps the control of aggressive behavior in "higher" organisms is an extension with variations on this theme.

## Aggressive Mimicry

Fiona R. Cross

School of Biological Sciences, University of Canterbury, Christchurch, New Zealand  
International Centre of Insect Physiology and Ecology, Mbita Point, Kenya

## Definition of “Aggressive Mimicry”

This is a term used when predators make signals that indirectly manipulate the behavior of their prey. Aggressive mimicry can be thought of as being a type of communication, as it involves two individuals (i.e., a sender and a receiver) and a signal, but in this instance the sender does not communicate to share information with the receiver in a reciprocal way. Instead, the sender uses specific signals to play mind games with the receiver, with the response elicited being detrimental to the receiver but beneficial to the sender. This type of communication is manipulative in an indirect way because, instead of being based on the sender physically forcing the receiver to do something in particular, it is based on assisting the sender with gaining indirect control of the receiver’s behavior (Jackson and Cross 2013).

## Mimicking Potential Prey

One of the most well-known examples of a predator indirectly manipulating the behavior of its prey comes from anglerfish, these being large deep-water fish species that prey on smaller predatory fish which, in turn, prey on small invertebrates. To communicate with their prey, anglerfish twitch fleshy spines extending in front of their mouths in ways that appear to resemble the stimulus the smaller predatory fish normally get from their own prey. When the smaller fish inspect the source of the signal, they are attacked and eaten by the anglerfish (Wilson 1937).

There is still much to be learned about how and why the anglerfish’s signals work, but more is known about caudal luring, a predatory strategy

used by snakes to exploit the prey identification systems of their prey, often lizards. When luring its prey, a snake may move its tail in characteristic ways that resemble the wriggling of caterpillars and other worm-like insect larvae that the lizards eat. However, puff adders also deploy lingual luring by moving their tongues in characteristic ways that lure amphibian prey (Glaudas and Alexander 2017).

Other important insights into how predators communicate with their prey come from considering invertebrates that specialize at preying on spiders. In these scenarios, having specialized strategies is essential because the tables can turn at any moment, with the hunter becoming the hunted. For example, when *Stenolemus bituberus*, an assassin bug reaches the edge of a spider's web, it lures the resident to within striking range by plucking the silk strands in ways that appear to mimic the movements made by a struggling insect (Wignall and Taylor 2011). Such a strategy is feasible because many spiders see poorly and rely on using their webs as an extension of their sensory systems. This means that, by stepping on to a web, a predator can directly manipulate a part of its prey's sensory apparatus (Jackson and Cross 2013).

There are, however, some spiders that are known to have excellent eyesight and actively hunt for their prey. *Portia* is a genus of jumping spiders (family Salticidae) from Africa, Asia, and Australia that specializes at preying on other spiders, and part of what it means to say that *Portia* is "specialized" is that this predator uses flexible strategies for communicating with its prey. After reaching the edge of another spider's web, *Portia* makes web signals by using any one or any combination of its eight legs and two pedipalps (Tarsitano et al. 2000), and it varies these signals according to the type of prey encountered. For example, *Portia* has an innate predisposition to use particular signaling routines when encountering some of its more common prey, but it relies on using trial-and-error during encounters with other prey (Jackson and Wilcox 1993). It also flexibly adjusts its signals according to feedback from the prey, such as by using trial and error to make signals that slowly lure in a more dangerous spider (Tarsitano et al. 2000).

## Mimicking Potential Mates

Some predators also succeed in prey capture by resembling the potential mates of their prey. For example, male *Photuris* and *Photinus* fireflies use species-specific flashing signals for finding mates, with the intervals elapsing between the male's flashing signal and the female's flashing reply usually being species-specific. However, once a *Photuris* female has mated, she starts answering the flashing signals from *Photinus* males and starts adopting the inter-flash interval characteristic of *Photinus* females rather than the inter-flash interval of her own species. In this way, she lures in the *Photinus* male close enough to attack, kill and eat him (Lloyd 1975).

In another example, females of *Euryattus*, a salticid species from Queensland, Australia, use dead rolled-up leaves for nests which they suspend from vegetation or from rock ledges using heavy silk guy lines. When a *Euryattus* male courts a potential mate, he walks down a guy line, positions himself on the leaf, and then shakes the leaf by suddenly flexing all his legs at the same time. The female cannot see the male while she is inside her leaf nest, and she emerges either to mate or to drive the male away. However, a spider-eating salticid from the same habitat, *Portia fimbriata*, will also walk down a guy line, position itself on the leaf, and then make leaf-shaking signals that resemble those made by *Euryattus* males. In these instances, when the female emerges from her nest, she is greeted by a predator instead of by a potential mate (Jackson and Wilcox 1990).

These examples show how aggressive mimicry strategies can become entangled with mating strategies, but the predator and prey can also be conspecific individuals. For instance, salticid courtship displays are often highly visual and, when a subadult (i.e., a juvenile that is one molt short of maturity) female of *Portia labiata* encounters a conspecific male, she displays in ways that resemble a mature female. However, as a subadult, this female is physically incapable of mating. When an adult male courts and attempts to mate with her, she makes a predatory attack on the male (Jackson and Hallas 1986).

## Chemical Mimicry

Although many examples of aggressive mimicry are visual, bolas spiders deploy chemical aggressive mimicry to capture male moths. These spiders emit from their bodies a particular blend of compounds that match the pheromones used by the females of their prey. When a male moth approaches, the spider whirls its bolas (a single line of silk with a drop of sticky glue at the end) to capture and reel in its prey.

Bolas spiders can attract more than one species of male moth, with *Mastophora cornigera* attracting as many as 19 different moth species. Another bolas spider, *Mastophora hutchinsoni*, mainly eats two moth species, *Tetanolita mynesalis* and *Lacinipolia renigera*. These two moths differ in their activity periods, with *L. renigera* being more active earlier in the night and with *T. mynesalis* being more active later in the night. To capture both species in a single night, *M. hutchinsoni* releases analogues of both moth species' pheromones, but it reduces its emission of the *L. renigera* pheromone blend as the night progresses. In doing so, *M. hutchinsoni* can capture *T. mynesalis* during later evening hours without reducing its capture rate of *L. renigera* during earlier evening hours (Haynes et al. 2002).

## Conclusion

The examples presented here are all of predators providing stimuli that indirectly manipulate the behavior of their prey. In all of these instances, the word “information” can be substituted with “misinformation,” as the elicited response to a given stimulus is advantageous to the sender and disadvantageous to the receiver. The sender can be thought of as behaving like a wolf in sheep's clothing, and yet there are differences in how taxonomically precise the sender's stimulus may be in “mimicking” a particular model. The anglerfish and snakes, for example, send signals that may mimic prey, but not particular species. Predators that mimic potential mates may be more

precise, as they send signals that are relevant in particular male-female interactions. However, for understanding what a predator is “mimicking,” it is especially important to consider the prey's own classification system rather than formal scientific taxonomy (see discussion in Jackson and Cross 2013). Often, a taxonomically precise model may not be necessary when eliciting a response that is favorable to the predator.

In the context of cognition, predators that raid webs can give us particularly important insights. The outcome of an aggressive mimic's “misinformation” can have life-or-death consequences for both the predator and the prey and, in these instances, having a rigid routine is potentially fatal for the predator. Instead, successful outcomes may often depend on the predator being flexible, which means that the predator needs to have the capacity to make decisions and to use trial-and-error for tailoring a particular signal to a particular kind of prey. In other words, although aggressive mimicry is usually considered in the context of animal communication, flexibility and deception are important expressions of animal cognition as well.

## Agonism and Social Status

Sarah M. Huskisson

Lester E. Fisher Center for the Study and Conservation of Apes, Lincoln Park Zoo, Chicago, IL, USA

## Definitions

Agonism is the collective term for social behaviors related to fighting (e.g., physical combat, displays, threats) and connected to resource competition or social status. An individual's social status may be determined by myriad factors, like dyadic interactions. Often, individuals that successfully utilize agonistic behaviors obtain high status within their social group, although high social status may also be gained via more pacifistic means (e.g., by forming positive social bonds or alliances) or inherited.

## Agonism

Agonistic behavior includes a range of defensive and aggressive behaviors that promote individual

survival and fitness. They fall under three main categories of behaviors: display/threat, aggression, and submission/avoidance.

Displays and threat behaviors are intended to make a competitor appear more physically capable, stronger, or larger than another (Manning and Dawkins 1998). Displays take the place of direct fighting, and animals who convey their strength through gestures reduce the cost of physical aggression. Frill-necked lizards (*Chlamydosaurus kingii*), for example, communicate their size by fanning out neck skin, making their heads look larger and flashing bright red and orange scales at opponents. This display is usually accompanied by head-bobbing, arm-, and tail-waving. Frilling is often seen in ritualized disputes during mating season (Shine 1990).

Direct aggression is most often seen when competing individuals are of similar size. Usually these fights do not escalate to the point of causing extreme injury, although possible, particularly if they are between members of different groups. In black mambas (*Dendroaspis polyepis*), fights consist of wrestling bouts, where one male attempts to pin another's head to the ground in order to win mating rights (Fogden 2000).

Submission is when one individual attempts to avoid injury from a dominant conspecific through a series of conciliatory displays. These often involve the submitting animal presenting a vulnerable part of its body to a dominant individual, sometimes incorporating behaviors derived from infant dependency or sexual solicitation. While some are simple, such as when dogs or wolves (*Canis sp.*) cower to dominant individuals (Schenkel 1967), some involve elaborate gestures, like bearded dragon (*Pogona vitticeps*) arm-waving (often seen in adolescents submitting to adults) (Grenard 2007). Similar to submissive behaviors, avoidance behaviors are inherently self-preserving; they reduce energy expenditure and risk of injury as animals typically avoid outright combat. If the costs to an animal are too high, avoiding a fight is the preferred option.

## Influences on Agonism

Agonistic behavior can begin in the brain, endocrine system, or genes. Within the brain, neocortical and subcortical structures control aggression (Purves et al. 2001). The amygdala is a structure with great power over agonism. When stimulated, it can increase aggression and when damaged, it can suppress associated dominance behaviors. The presence and concentration of androgens (specifically testosterone) can also significantly influence agonism in individuals. Levels of androgens may be influenced by an individual's age, rank, sex, and/or breeding status. Glucocorticoids (GCs), hormones associated with stress, are also responsible for agonism in animals. In cichlid teleost fish (*Aequidens pulcher*), cortisol notably increases the performance of submissive behaviors in agonistic interactions, which indirectly increases aggression (Munro and Pitcher 1985). A high prevalence of glucocorticoids may promote agonism, thus further facilitating the development of social hierarchies, which will be discussed in the following sections.

## Social Status

In social species, group members often have differential ranks, meaning individuals or kin groups are dominant over others, defining their social status. An individual's social status determines access to resources, reproductive opportunities, and, in some cases, ability to control part or all of the group.

Depending on the animal society in question, status may play a greater or lesser role among the species' social system. Some societies, such as hyena (*Crocuta sp.*), exhibit a linear dominance hierarchy, or pecking order, in which each individual within a group is either dominant or submissive relative to another member of the group (Watts and Holekamp 2007). Other species, like gorillas (*Gorilla sp.*), maintain a despotic social system, in which all members are equally submissive to one leader (in this case, the silverback male). African painted dogs (*Lycaon pictus*) and

meerkats (*Suricata suricatta*) are other despotic species (Alcock 2005). Still other species are egalitarian in their social relationships, where rank plays a minimal, if any, role in intrasexual interactions (e.g., northern muriqui (*Brachyteles hyppochanthus*) (Mitani et al. 2012).

A variant of ranking exists in eusocial species, where group members are a part of a caste system and belong to a certain role or occupation, determined at birth. Examples of eusocial animals include honey ants (*Myrmecocystus mexicanus*), naked mole rats (*Heterocephalus glaber*), and honey bees (*Apis* sp.) (Andersson 1984). In a caste system, reproductive rights and resource access are divided according to “duty.” In other words, those that perform a “lower” kind of work will not have the same opportunities as those in more elevated positions, despite working cooperatively as a whole unit. Yet, unlike the other forms of social structure discussed above, individuals of a certain caste generally lose behaviors or characteristics that are often found in other castes.

## Influences on Status

Social status may be heavily influenced by the social environment, particularly an individual’s involvement in dyadic interactions (typically intrasexual) with other members of its group, as well as relatedness to others and group tenure. The quality and outcome of these interactions provide a method for better understanding an individual’s place in their respective society. After an animal’s “place” is established, they do not need to fight for resources each time they meet. Huntingford (1984) identified three overarching types of interactions that can determine status: resource-holding potential, investment in the resource, and “ownership” of the resource (i.e., home-territory advantage). Ultimately, those who value a given resource more than their competitor are predicted to achieve dominance over that competitor.

In addition to the social environment, an individual’s intrinsic characteristics may also

influence their social status. For example, social status has been linked to cognitive function, in that socially dominant individuals display greater accuracy on cognitive tasks and vice versa (i.e., causality is unclear). This is seen in pheasants (*Phasianus colchicus*): chicks that perform well on cognitive tasks are also more likely to obtain higher rank among conspecifics (Langley et al. 2018). It may also be the case that inherent personality traits influence status, as shown in rainbowfish (*Melanotaenia duboulayi*) (Colleter and Brown 2011).

Social status has also been connected to physiological and genetic mechanisms. In some species, animals inherit status, in the form of ordinal rank, from their parent(s). Many monkey species, like rhesus macaques (*Macaca mulatta*), inherit rank from their mother (Vandeleest et al. 2016), while male Canada goose (*Branta canadensis*) chicks’ rank is based on the rank of their collective family (Raveling 1970). Other studies have noted the interconnectedness of status, agonistic interactions, and GC levels. In wolf (*Canis lupus*) populations at Yellowstone National Park, high-ranking individuals exhibited higher GC levels, posited to be associated with their need for readiness to preserve their rank. Additionally, high GC levels coincide with rank stability, not necessarily rank order (Sands and Creel 2004).

## The Intersection of Agonism and Social Status

Animals of low rank not only experience reduced access to resources but also exhibit reductions in health and well-being. Animals that are more willing and able to initiate disputes with group members are more likely to defend territory, mates, or other resources, and consequently gain and maintain elevated status. High-ranking individuals typically use agonism to keep group members “in check,” presenting the opportunity for lower-ranking individuals to receive extensive and possibly unprovoked displacement aggression. In a study of red junglefowl (*Gallus spadiceus*), lower-ranking individuals were most often pecked

by higher-ranking group members, in spite of the lower-ranked individual initiating allopreening (i.e., grooming) (Vestergaard et al. 1993). Such prolonged aggression can have direct and indirect consequences on subordinates' health and wellbeing (e.g., Snyder-Mackeler et al. 2016). Increased aggression between group members and/or in connection to social status appear to be a problem also for managed wildlife (e.g., Sands and Creel 2004). In contrast, for some species, stability in status, rather than relative rank and status, contributes to enhanced welfare and health (e.g., *M. mulatta*, Vandeleeest et al. 2016).

Animals of low rank who receive more agonistic attention from peers may also experience the suppression of neuroendocrine function. Stress inhibits the parasympathetic nervous system, subsequently halting hormone production that aids in digestion, reproduction, and growth. Stress responses like this are adaptive in situations where "fight-or-flight" is necessary to maintain internal homeostasis. However, a chronic stress response can lead to the acquisition of disease and other dysregulation. The energy expelled following a stressor is not stored, causing organs and physiological functions to work overtime, wearing them down. Long-term, chronic stress, and wasted energy can lead to muscle atrophy, hypertension, and fatigue, among other issues that may lead to an overall compromised wellness (Sapolsky 2004).

## Comparisons with Humans

Among humans, status persists in nearly every social group. Even as young children, our interactions with others begin to determine our rank within classrooms, friend groups, and future interactions (Garandean et al. 2014). This can influence our emotional states, which could then affect future interactions with others. Particularly in children, social hierarchies may promote the victimization of and aggression toward low-status individuals (Garandean et al. 2014). It has been argued that socioeconomic status among adults is the closest approximation to a true dominance hierarchy in our species. This argument is

bolstered by evidence that socioeconomic status influences individual health due to access to resources like medical insurance (Sapolsky 2004). As seen in animals, humans can experience reduced quality of life and well-being dependent on their social status.

## Conclusion

Across species, agonistic interactions lie at the heart of social status, and both act upon one another to shape the lives of gregarious animals. While agonistic interactions may help individuals assert themselves as leaders among other members of their species conferring benefits, the maintenance of elevated rank is also not without cost. It is also important to remember that, for many species, social status is an emergent property: and individual's rank is depending on their social environment and is thus dynamic, with the potential to change over time.

## Synonyms

Aggression; Agonism; Dominance

## Definition

Agonistic behavior is any social interaction or engagement, which involves threatening behavior, aggression, fighting, or submission.

## Overview

Agonistic behavior is commonplace across the animal kingdom. It can be described as a suite of social behaviors related to any form of aggressive or fighting actions, which occur between two or more individuals of the same species and therefore exclude predator-prey interactions. Agonistic behaviors play an important role in shaping both an individual's life history in solitary species and group structure in gregarious animals. These behaviors can be categorized into three main components: threat, aggression, and submission. All three are interrelated and can occur in combination or alone. The most common agonistic behaviors occur over access to a certain resource, such as food, shelter, and territory, or access to a mating partner. These agonistic behaviors can range from very mild, such as fleeing another individual, to severe physical fighting which can even lead to death (Maynard Smith 1974). Many animal

species have developed ritualized displays so that an escalation of contest between two individuals is not always necessary and two opponents can decide on their likelihood of victory beforehand. An agonistic interaction is only likely to occur if the disputed resource is of sufficient magnitude to induce competition. If a resource is common, evenly distributed, or of low value, it is unlikely that agonism will transpire. The rates at which agonistic behaviors occur within a given species, population, community, or social group can depend on many factors ranging from spatial position of individuals, to the number of individuals present, to the distribution of the resource and the condition of the individuals involved. A suite of sex steroid hormones, including androgens, mainly regulates agonistic behavior.

### Threat Behavior

Threat behavior may be exhibited by one individual to another in order to show their intent to be aggressive. Threat behaviors include but are not limited to vocalizations, facial threats, physical movements toward an opponent, and posturing to show ones physical attributes. Threat behaviors do not include physical contact. Threat behaviors are a method to show ones discontent without resulting in full escalation of a contest into physical aggression. Threat behaviors should lead to the target of the behavior to back down (show submission) and leave the contest before it escalates, or if not then potentially costly physical aggression will most likely occur. These threats are often displays of intimidation where an individual will try to emphasize their size or weaponry to attempt to make their opponent show submission. The extent to which outcome is likely to escalate depends on the motivation of the two opponents and the resource in question.

Threat behaviors include ritualized displays within the animal kingdom, in which individuals can convey multimodal information to others. In terms of agonistic aggression, this can be a low-cost method for individuals to decipher the size and strength of an opponent. These displays can range from body size or weaponry (e.g., size of

antlers in ungulates or canine size in nonhuman primates; Clutton-Brock 2009) to stereotyped signals. Visual signals can range from facial threats in primate species to colorful displays of fish and cephalopods. Furthermore, chemical signaling such as scent marking or information contained in urinary secretions in fish can also act as a means to convey an individual's prowess. Individuals can assess their opponent from at a distance and decide if physical contest is required. Depending on the signal strength and quality, the opponent may not be necessarily present, for example, vocalizations, scent marking, or urinary secretions can all advertise information for one individual to another without the advertiser being visually present. These threat behavioral cues can therefore also advertise a territory and allow weaker individuals to avoid areas where they know stronger conspecifics are residing. Such behavior can be valuable in two ways: firstly, it can save individuals' time as they do not need to constantly engage in aggressive contest with every opponent they come across, and secondly it can save individuals' energy and potential risk of injury. These ritualized displays can be used as a proxy for overall strength and reduce the possibility of escalation into a full fight which could cause major injury to one or both of the contestants. For example, many male songbirds produce complex vocalizations to mark their territory with louder calls showing greater strength, and other males in the area can decide if they wish to engage in an aggressive conflict after hearing the song, and insects use vocalizations to defend resources (Wingfield et al. 1987).

### Aggressive Behavior

Aggression is a term which can be defined and interpreted in various ways. Here, aggression is referred to as an act or behavior by one individual, which inflicts physical harm to another. Historically, studies investigating aggression in males have focused on a sexual context, either aggression between males to gain mating access to females or territory defense, as males aim to fertilize as many females as possible to maximize

reproductive success (Clutton-Brock 2009; Trivers 1972). Whereas research into female-female aggression has focused on access to resources, such as access to clumped food resources, access to males, or territory defense, as females generally invest more heavily in fewer offspring (Clutton-Brock 2009; van Schaik 1989). Males have been considered to be more aggressive than females in the historical literature as males must outcompete one another to access a non-divisible resource (estrous females). However, females can be equally aggressive and have been shown to compete for access to resources even to a lethal level. Fights between female matrilineal social groups can lead to severe injury or death of several individuals in nonhuman primates. Access to food resources is considered one of the main drivers of female reproductive success and as a result is one of the main contexts under which female conflict occurs. Several socioecological models state that within-group feeding competition between females shapes their group structure. Depending on the rate at which resources can be depleted and the level to which resources can be monopolized determines the severity and frequency of conflict within the social group (Clutton-Brock 2009; van Schaik 1989). Male reproductive success is generally driven by competition for access to estrous females, and as a result direct competition between males is the main form of conflict observed (Clutton-Brock 2009; Trivers 1972). The intensity can vary depending on if the species in question are seasonal or nonseasonal breeders. Seasonal breeding species have a defined window within which all females will be in estrous, and so male-male competition is high during these mating seasons. This leads to periods of high and low intensity and frequency of conflict between males. Whereas for nonseasonal breeding species, females can be in estrous at any time of the year, and so male competition for access to females is more unpredictable.

Aggression also occurs between males and females. Due to direct male-male competition, there is often large sexual dimorphism in many species, where males show greater physical attributes (such as body size and weaponry). This

means males are often able to win agonistic contests against females. However, depending on the motivation and context of the situation, females do win contests against males. For example, in some nonhuman primate species and spotted hyenas (*Crocuta crocuta*), females frequently win fights against males and are dominant over some or all of males in their social groups (East et al. 2003; Kappeler 1993; Young et al. 2017). Females can reject mating opportunities with males in some species and can use aggressive contests to protect their offspring and avoid infanticide (Clutton-Brock 2009). Aggression can occur between social groups to maintain their territory and in extreme circumstances can even lead to lethal aggression between groups, such as in chimpanzees (*Pan troglodytes*, Watts et al. 2006).

Dominance refers to the chance of one individual winning a fight over another and usually occurs over a limited resource (such as food, mating opportunities, or territory). Dominance can occur between solitary and group living individuals and even between groups. A dominance hierarchy or rank structure occurs after repeated interactions between two individuals over time, whereby the winner and loser of the contests can be ordered. The majority of agonistic aggression observed occurs between two individuals and is thus dyadic agonistic contest (Drews 1993). Overall, dominance within groups acts to allow individuals a priority of access to certain resources or commodities. This can include food, shelter, mates, or the spatial position within a social group for predator avoidance. Therefore, individuals in gregarious species strive to achieve as high a social status (position in the dominance hierarchy) as possible to infer such benefits. It is worth noting that physical attributes and weaponry alone are not always the deciding factors in dominance rank acquisition. Several other factors such as social alliances can play a large role. In some species, including several primate species, several additional factors such as strong social relationships with other group members (males and females) can improve an individual's rank position (Smith et al. 2010). Forming strong bonds with other group members can lead to coalitionary

alliances where individuals come to each other's aid during aggressive contest. This is known as agonistic or coalitionary support. As females are often the philopatric sex in primate species, females often support kin within social groups (Chapais 1995). This can be against other females or against males within their social group. Males are also observed to form coalitions; these can be with females against other males or between males. Male coalition formation can range from opportunistic support where a male joins an ongoing dyadic contest between two opponents or can be coordinated where two individuals target a specific opponent. These coalitions can occur in two main contexts: firstly, "leveling" coalitions whereby individuals break up male female consorts or mating opportunities to level the mating skew in a group and secondly "revolutionary" or rank related coalitions, whereby individuals join forces to usurp a higher-ranked individual (van Schaik et al. 2006; Young et al. 2014).

As conflict can be commonplace in group living animals, conflict resolutions have been observed in various forms in order to restore or repair relationships after a conflict has occurred. It is thought that such behaviors can act to appease the negative impacts of aggression from one individual to another and maintain group cohesion and stability. This is particularly common among related individuals within a social group to repair the damage of an aggressive interaction (Aureli et al. 2002). Individuals may also attempt to redirect an aggressive act; under such circumstances an individual who has received aggression will redirect such aggression to another group member who is close by. This is most often a subordinate group member, and it acts to reduce the chance of further aggression to them and moves the attention of the aggression to another individual.

### Submissive Behavior

Generally submissive behavior goes hand in hand with aggressive behavior and is a clear signal given by the loser of an agonistic contest to their opponent that they no longer wish to carry on the contest. These signals can be very clear such as

fleeing from an opponent to avoid the conflict altogether or to avoid further escalation of an ongoing conflict. However, submissive behavior can be much more subtle, for example, one individual can approach another and merely displace it from a given resource, such as a feeding patch. During such interactions the "aggressor" need not show any actual aggressive behavior, but their mere presence alone and approach toward the other individual is enough for them to give up their resource and move away. Such interactions show a clear understanding of an individual's relative strength and knowledge. Avoidance behavior can be beneficial, as it does not allow a fight over a resource to break out which could lead to serious injury. By giving clear submissive signals, weaker or lower-ranked individuals can avoid conflict with more powerful opponents.

### Agonistic Behavior and Hormones

Aggressive behavior is physiologically regulated by a suite of different steroid hormones; these include a range of sex hormones (such as androgens and estradiol) which can increase aggressive behavior and serotonin which acts to decrease aggressive behavior. In particular testosterone has been shown to play a major role in promoting aggressive behavior in a range of species. This was first shown in experimental studies by Berthold in 1849 on roosters (male chicken, *Gallus gallus domesticus*; for a full description, see Soma 2006), where castrated roosters showed low aggression rates, little interest in mating, and a decrease in secondary sexual characteristics compared to non-castrated roosters. In territorial bird species, increases in display behavior at the start of spring (start of the breeding season) are linked with increases in luteinizing hormone and testosterone above baseline levels (Wingfield et al. 1987). These increases in hormonal output increase male competitive behaviors and as a result aid them in competing for a mate and then guarding their nest and mate against other male intruders. However, some bird species show high levels of agonistic behavior outside of the breeding season when testosterone levels are low; here

it has been shown that estradiol is the steroid which mediates agonistic interactions in birds (Soma 2006). Further research is required to see if this is the case for other species too. Indeed the link between testosterone and aggression in both human and nonhuman primates remains ambiguous and also requires further research.

The challenge hypothesis states that in periods of social instability, testosterone and aggression are correlated (Wingfield et al. 1990). In seasonal breeding species, for example, the challenge hypothesis posits a link between testosterone secretion and aggression. Seasonal patterns of testosterone secretion are observed in males where testosterone increases before the breeding season (or when a female is in estrous) in order to increase the competitive ability of the individual for mating competition. However, the challenge hypothesis suggests that due to competition between males for females, testosterone secretion will increase to maximum levels which in turn will increase the tendency for males to aggress one another. This heightening of aggressive contest due to rising testosterone only occurs in a mating contest, and outside of such times, male relationships are maintained via other means such as recognition of other individuals' attributes and the dominance hierarchy. Research in chimpanzees (who breed all year round) also showed support for the challenge hypothesis with aggression rates and testosterone levels increasing whenever a female was in estrous. This suggests that the challenge hypothesis is not just applicable to seasonal breeders (Muller and Wrangham 2004).

## Conclusion

Agonistic behaviors occur across almost every taxa of the animal kingdom. These behaviors can range from subtle threat behaviors to full physical contest and even lead to death. The extent to which an agonistic contest will escalate depends on the value of the resource being contested, the motivation of the competitors, and the level of similarity in attributes between the opponents. As physical contest is costly both temporally and energetically, many species have evolved

ritualized behaviors in which to assess an opponent before engaging in physical contest. This also reduces the risk of physical injury or death. Overall, agonistic behaviors play an important role in shaping individual life histories for solitary living species through gregarious social species and ultimately shape the wide range of social and mating systems observed today.

## Ai (Chimpanzee)

Tetsuro Matsuzawa  
Kyoto University, Kyoto, Japan

Ai is a female chimpanzee who has been the research partner of Prof. Tetsuro Matsuzawa of Kyoto University, Japan, for more than four decades. Ai has participated in many different cognitive tasks over the years, allowing researchers to compare her performance to that of human subjects, under the umbrella of comparative cognitive science.

Ai is a West African chimpanzee (*Pan troglodytes verus*), a subspecies distributed across several countries including Guinea, Ivory Coast, Liberia, and Sierra Leone. She is thought to have been born somewhere in West Africa around November 1976. She was likely separated from her mother and shipped by an animal dealer from Monrovia, Liberia, to Japan. Japan only ratified CITES, the convention prohibiting the international trade of endangered species, in 1980; thus in the 1970s, it was still legal to import chimpanzees from the wild. Nonetheless, this does not diminish the distressing history of wild chimpanzees being caught and sold to zoos and biomedical facilities across North America, Europe, and Japan for decades.

Based on her pattern of dental eruption, researchers estimated Ai's age as approximately 1 year when she arrived at the Primate Research Institute of Kyoto University on November 10, 1977. This date marks the official start of the "Ai project." Initially, the Ai project was conceived as the Japanese answer to the "ape-language" studies popular in the USA at the time.

These studies, run predominantly by psychologists, aimed to elucidate the cognitive capabilities of young chimpanzees who were raised in

human environments. The best known subjects were the chimpanzees Vicky, Gua, Washoe, Sarah, Lana, and Nim, among others. Other apes included a gorilla named Koko, the bonobo Kanzi, and an orangutan named Chantek. Each of these apes was raised in a human environment and encouraged to interact with human partners. Communication and language were the central foci of ape-language projects. The media used for interactions between humans and apes included spoken language, gestural sign language, colored plastic chips, and specially designed pictograms called lexigrams.

When the Ai project started, we already had some understanding of apes' capability to learn rudimentary forms of human language. The Ai project was unique because it did not focus on communication but instead on the psychophysical measurement of perception, cognition, and memory. In other words, the key question was how the world was perceived by a chimpanzee. Importantly, using the same apparatus and following the same procedure, the performance of the chimpanzee participants could be compared directly with that of human subjects.

Ai first learned the names of eight familiar objects: pencil, toothbrush, wooden block, glove, bowl, paper, lock, and key. The names she learnt were lexigrams, i.e., geometric figures, built from nine basic elements: horizontal line, orthogonal line, wave, vertical wave, small solid circle, small solid lozenge, large open circle, large open lozenge, and open square. Each lexigram, constructed by combining two or three of these basic elements, corresponded to one of the objects. Besides Ai, two other young chimpanzees – Akira and Mari – also participated in the acquisition of object names. The procedure involved a so-called symbolic match-to-sample task: when a specific object was presented to the chimpanzees, they had to choose the corresponding lexigram from a keyboard in order to name it.

On April 15, 1978, Ai pressed a key on the keyboard for the first time. She mastered the symbolic match-to-sample task for all 8 objects in 57 daily sessions over a period of 2.5 months. Akira took 83 sessions, and Mari took 104 sessions.

Thus, it became clear that there were pronounced individual differences among our students.

The three young chimpanzees mastered color names too. They were taught 11 different colors: red, orange, yellow, green, blue, purple, pink, brown, white, gray, and black. The names were again lexigrams. For example, the color red was represented by a lexigram combining an open lozenge and a horizontal line, while blue was a large open circle combined with a small solid circle. By asking the chimpanzee Ai to name a variety of different colors – the 224 color chips of the Munsell color system representing different hues, brightnesses, and saturation – using her “vocabulary” of color lexigrams, her color perception was shown to be very similar to that of humans. Chips from color boundaries, such as reddish pink or bluish green, elicited longer response times from both humans and Ai. In sum, the basic color categorization system found in humans is shared with chimpanzees.

Ai also learned the 26 letters of the alphabet. These were used to measure her visual acuity, determining the threshold by changing the size of a given letter placed at a distance of 3 m. Ai's binocular visual acuity was about 1.5, comparable to that of human subjects. Once she was able to discriminate the letters, she was taught to use specific ones as labels for familiar chimpanzees and humans. Asking Ai to name individuals from photographs by choosing the corresponding letters revealed that it was easier for Ai to discriminate chimpanzees than humans (much like it is easier for humans to discriminate other humans than chimpanzees).

Ai was also the first chimpanzee who mastered the skill of using Arabic numerals to label numbers of items. For example, when six pencils were shown in a display window to Ai, she would correctly choose the numeral 6 on the keyboard. Even more, she combined her naming skills to describe the number, color, and identity of a sample of objects at the same time. Suppose that five red pencils were shown to Ai: she pressed three keys, “5,” “red,” and “pencil,” consecutively. Interestingly, this led to a unique finding in the form of spontaneously preferred “word order.” Ai was free to press the three keys in any order, yet

her preference was to choose either the object name or the color name first and always choose the number last. This spontaneous tendency is reminiscent of a rudimentary grammatical rule.

Thanks to collaborators such as Masaki Tomonaga, Kazuo Fujita, and Shozo Kojima, Ai also participated in many other computer-based tasks exploring topics such as visual search, mental rotation, face inversion effect, delayed memory, metacognition, auditory threshold, visual-auditory synergy effect, understanding tempo, and so on. Touch-sensitive monitors were used not only to record single responses but also to shape touch-and-drag behavior allowing line drawing and the sorting of objects into multiple categories. Other input media, such as a drag ball, were later introduced, and even a piano keyboard was used for cognitive tests.

The original Ai project is centered on a paradigm in which a single chimpanzee faces a single computer monitor. However, in subsequent stages of the project, researchers became interested in social aspects of intelligence and in tasks that involved real-life objects and individuals. Thus the laboratory shifted away from using single booths for testing to using dual booths, then to triple booths, and even to testing chimpanzees in the outdoor compound where they lived with their groupmates. Masako Myowa-Yamakoshi studied imitation and discovered that chimpanzees found it difficult to reproduce simple actions if these did not involve objects. Shinya Yamamoto studied collaboration and discovered that chimpanzees found it difficult to help out a partner in the neighboring booth.

This paradigm shift from single subject to social setting may have been driven by researchers of the laboratory being encouraged to visit chimpanzee field sites in Africa to observe the real lives of these apes in their natural habitat. Many of them went to Bossou, Guinea, West Africa, where Prof. Matsuzawa has established his field studies. Bossou chimpanzees are known to have a unique culture that includes the use of a pair of stones as hammer and anvil to crack open oil palm nuts. Chimpanzee society in the wild is structured around a rich social network, within

which the strong mother-infant bond is especially important. In such communities, chimpanzees pass on skills, techniques, and values from one generation to the next. The process through which such knowledge is acquired via observational learning has been described as “Education by master apprenticeship.”

In 2000, when Ai was 23.5 years old, she gave birth to a son named Ayumu on April 24. In the same year, two more female chimpanzees at the Primate Research Institute gave birth: Chloe to a daughter named Cleo, and Pan to a daughter named Pal. With these births, the focus of the Ai project changed once again, now to the three mother-infant pairs. The new focus is best described as comparative cognitive developmental science (CoCoDev science). The 3 pairs were members of a group of 14 chimpanzees of 3 different generations, including 3 adult males, 8 adult females, and 3 baby chimpanzees. They lived in an enriched environment, a large outdoor compound with many trees, shrubs, and grasses, and 15-m-high climbing frames built in 1998. Two huge, 16-m-high cages were connected to the outdoor compound in 2012. This complex habitat afforded the chimpanzees two kinds of fundamental freedom: the freedom to move and the freedom to eat. They split into small parties and freely visited different parts of their habitat. This process simulates the fission-fusion grouping dynamics that is characteristic of chimpanzees in the wild.

From the time the three baby chimpanzees were born in 2000, the Ai project introduced the technique of participant observation. This is a unique way of the study that unites three components: a researcher, a mother, and a child. The researchers entered the chimpanzee testing rooms and interacted with the mothers and their infants – in a sense, they participated in the daily lives of the chimpanzees. Thanks to the long-term friendship between researchers and the mother chimpanzees, the researchers were able to ask the mothers to help them test their offspring. There were three such researcher-mother-offspring trios: Matsuzawa-Ai-Ayumu, Tomonaga-Chloe-Cleo, and Tanaka-Pan-Pal. Matsuzawa was able to participate in the testing of all three chimpanzee

pairs. Misato Hayashi also joined to test three children.

In the Western tradition, researchers frequently separated baby chimpanzees from their mothers. The isolated babies were then raised in a human home, and their cognitive development is studied. The logic was that by keeping the rearing conditions the same as that of a human infant, any differences observed could be attributed to innate species differences. However, chimpanzee babies isolated from their mothers often exhibited signs akin to depression. They were forced to adapt to a human environment. Not only was this a highly abnormal situation, but it is clearly unethical to separate a baby from its mother. As an alternative, the participant observation approach of the Ai project brought new insights into our understanding of the mother-infant relationship in chimpanzees.

Chimpanzee babies start to recognize their mother's face at around 1 month old. They show facial gestural imitation just like human babies. They start to understand pointing, even to distant targets behind them. Mothers share food with their offspring, although active sharing is rare: it is most often the offspring who initiate the sharing. Satoshi Hirata has focused on the acquisition of tool use. Observational learning of tool use, such as "fishing" for honey, mirrors the education by master-apprenticeship model that was originally postulated for chimpanzees in the wild. There is no active teaching from the mother, but the offspring have an intrinsic motivation to copy the adults' behavior. As the young grow, not only the mother but also other adults become important sources of information and skills for them. Claudia Sousa showed that Ayumu the son started to use tokens for the vending machine at 2 years old after observing the mother Ai's behavior after the birth. This age is somehow corresponding to the first onset of tool use in the wild such as use of leaves for drinking water.

Among the various cognitive capacities explored in the Ai project, the most impressive finding was the extraordinary working memory of young chimpanzees. Dora Biro, Nobuyuki Kawai, and Sana Inoue were involved in the

endeavor to characterize chimpanzees' unique memory. Ai was the first chimpanzee who mastered the so-called masking task to test her recall. In this task, a set of Arabic numerals between 1 and 9 appeared at random locations on the touch monitor. After the subject touched the smallest number, the other numerals were replaced by white rectangles. To solve the task, the subject had to touch the rectangles in the order that corresponded to the ascending sequence of the numerals originally displayed. The three young chimpanzees were excellent at this task, while adult chimpanzees, including Ai, were as good as adult humans. However, Ayumu, the best performer among the three young chimpanzees, was outstanding even with as many as nine numerals: he made the first touch to "1" in less than 0.5 s (that is, he needed only 0.5 s to memorize the entire sequence), and his accuracy was more than 80%. No human subjects can match Ayumu's accuracy at this latency.

Chimpanzees can outperform humans in a cognitive task. This message is important. So far, other studies have successfully demonstrated chimpanzee intelligence in several domains such as tool use, drawing, and gestural sign language. But those skills are also human skills. However, in the case of numerical memory, chimpanzees' performance was better than humans'. For the first time, chimpanzees were shown to be better than humans in an intellectual domain. This kind of finding may help us to abandon outdated notions of a human-animal dichotomy. Humans are part of the animal kingdom, and every species in the animal kingdom has developed its own unique set of cognitive capabilities.

The chimpanzee Ai is a sort of icon of the Ai project, a holistic approach to understanding our closest living relatives. The project unites field-work and laboratory work. It has also contributed to other scientific disciplines such as genomics: the first chimpanzee trio genome comes from three chimpanzees at the Primate Research Institute, Akira the father, Ai the mother, and Ayumu the son. Each of about 3 billion base pairs was analyzed and we found 46 SNPs in one generation. Among the SNPs, three-quarters originated

from father's side while one quarter came from the mother side.

As of July 2019, there are 305 chimpanzees housed at 48 facilities in Japan. All the apes in Japan have been registered by the Great Ape Information Network (GAIN) project. The database is open to the public, allowing anyone to access individual records any time from any place. The database is renewed in real time when an individual dies or when one is born. The system facilitates postmortem utilization of specimens, thus reducing the need for biomedical study on live chimpanzees.

Ai turns 43 in 2019. Chimpanzees can live for 50 years or longer. She will continue to be an invaluable research partner who can reveal to us hitherto unknown aspects of the chimpanzee mind. For further information, please visit the HP:

## Alarm Calls

Shannon M. Digweed

Departments of Psychology and Biological Sciences, MacEwan University, Edmonton, AB, Canada

## Synonyms

[Alarm signal](#); [Alarm vocalization](#); [Antipredator call](#); [Antipredator signal](#)

## Definition

A loud sound emitted during any stage of a predator/prey interaction.

## Introduction

Predation is one of the largest contributors to natural mortality for all animals, and the persistent threat of predation thus exerts a major influence on behavior in many species. Different species respond to predatory threats in different ways. Some species adopt cryptic strategies to reduce detection by predators, whereas others focus on strategies to better detect the predators themselves and then either elude or confront them. One of the most common behavioral responses to predators involves the production of loud, conspicuous vocalizations, or alarm calls by prey species. Such calls are produced by many species of mammals and birds when they encounter predators and they can function to alert conspecifics to the danger and prompt appropriate escape responses in them that improves their survival (Sherman 1980), or they may communicate to the predator itself that it has been detected and that the probability of a successful hunt is requisitely diminished (Caro 1995). The underlying factors which lead to the production of alarm calls may be due to changes in affect or motivation (Morton 1977), the type of predator that is encountered (Evans 1997), or the urgency of response that may be required (Owings and Leger 1980).

## The Functions of Alarm Calls

Alarm calls tend to be among the loudest and most conspicuous calls in species' vocal repertoires. As a result, they represent a potentially risky behavior, because producing loud calls when a predator is detected almost certainly draws the predator's attention towards the caller itself. Therefore, those who call (as opposed to those who might remain silent) almost certainly increase their own risk of being preyed upon. In fact, among Belding's ground squirrels, individuals that produced alarm calls (8%) were more likely to be attacked than those who did not produce calls (4%; Sherman 1977). Nevertheless, alarm calling is very common among birds and mammals; therefore, it seems there must be some important benefits to calling that compensate for these costs. It is critical to ask, then, "What does an individual gain by producing alarm calls?"

Individuals that live in groups composed primarily of closely related kin might acquire inclusive fitness benefits from warning and potentially protecting relatives from predators (Sherman 1980). If true, individuals with kin nearby should call more than those without. In fact, research on several mammalian species supports this prediction (Blumstein 2007; Wheeler 2008). For example, among 13-lined ground squirrels (*Spermophilus tridecemlineatus*), adult females with offspring and collateral kin nearby, produce more alarm calls to terrestrial predators than do adult males with fewer direct and collateral kin nearby. Importantly, alarm calling is correlated with increased survival of offspring and close relatives (Schwagmeyer 1980). Similar results have been reported in black-tailed prairie dogs (*Cynomys ludovicianus*) and Columbian ground squirrels (*Spermophilus columbianus*), where breeding females that are surrounded by kin produce alarm calls at higher rates than do males or breeding females (MacWhirter 1992).

Alarm calling to warn kin may occur more widely. For example, among nonhuman primates, vervet monkeys are noted for producing a variety of conspicuous alarm vocalizations when they detect predators nearby. Like female ground squirrels, female vervet monkeys are also the

philopatric sex; hence, groups of vervet monkeys are comprised of related females (and their offspring) and unrelated, immigrant males (Cheney and Seyfarth 1990). Female vervets also tend to maintain close social bonds with their female relatives, while males are socially peripheral and interact predominantly only with adult females in estrus and with their own offspring (Cheney and Seyfarth 1990). If the alarm calls of vervet monkeys function to warn kin, as they seem to do in ground squirrels, adult female vervet monkeys should produce calls at higher rates than do males. Results indicate that, in fact, there is no difference in the calling rates of males and females (Cheney and Seyfarth 1981). However, high-ranking females with more kin in the group produce more calls than lower-ranking females with fewer kin. Furthermore, high-ranking males with more offspring were also found to produce more calls than low-ranking males with fewer offspring (Cheney and Seyfarth 1981). Although these results indicate that alarm calls are produced by both males and females in vervet monkeys, they nevertheless suggest that the production of alarm calls during predator encounters may have evolved through the kin-selected benefits associated with warning relatives about potential dangers.

Warning kin is not the only possible selected benefit associated with producing alarm calls, however. When survival of a mate is important to an individual's fitness, individuals may call to warn mates (Krams et al. 2006; Witkin and Ficken 1979). For example, Carolina wrens form pair bonds throughout the year and these pair-bond relationships are critical in maintaining and defending a breeding territory (Morton and Shalter 1977). When a female loses a mate, she can no longer maintain the territory and is quickly driven out by another pair. Because a female cannot defend a territory alone, it might benefit her to protect her mate from potential predators by producing alarm calls. In fact, results using a tethered hawk confirmed that female Carolina wrens produce significantly more "chirt" calls than do males (Morton and Shalter 1977). In contrast, in great tits (*Parus major*), it seems to be the males who produce alarm calls to warn mates. Males produce

alarm calls both within and outside their breeding ranges if a female is nearby but do not call when alone. This pattern suggests that male alarm calls function to warn potential mates of predators (Krams et al. 2006).

Alarm signals can function as warnings to kin or mates, but it is also possible that these signals can function to manipulate and potentially deter predators themselves (e.g. Caro 1995). Somewhat counterintuitively, prey species sometimes produce vocal signals that actually draw a predator's attention towards them. For example, primates produce loud alarm calls that may function to deter predators, particularly those that rely on stealth (Zuberbühler et al. 1997, 1999). Research on six different species of monkey in the Tai forest, Ivory Coast, shows that the monkeys are more likely to produce conspicuous alarm calls to predators, like the leopard, that rely on stealth (or ambush) to capture prey, and remain silent when they detect a pursuit predator (e.g., chimpanzees) that are comparatively undeterred by having been detected and instead rely on outpacing their prey (Zuberbühler et al. 1997). Furthermore, through observations of a radio-collared leopard, Zuberbühler et al. (1999) have shown that the alarm calls of the monkeys do have an effect on the predator; following natural vocalizations by the monkeys, or experimental playback of their calls, a radio-collared leopard was more likely to give up its hunt and leave the area.

## The Mechanisms Underlying Alarm Calls

An additional important focus of research on alarm call behavior concerns the underlying mechanisms that motivate the production of these signals and the associated issue of the potential messages that alarm calls convey to listeners. Here, a long-standing view is that alarm vocalizations often reflect the underlying motivational state (e.g., fear) of the individual encountering a predator (Morton 1977, 1982). Morton (1977) developed this view into a broader theoretical framework that relates the detailed acoustic structure of signals given in a variety of circumstances – including encounters with predators –

to the different states of arousal or motivation that they reflect, what he termed “motivation-structural rules.” Morton (1977) predicted, for example, that harsh, low-frequency sounds indicate aggressive motivations, while tonal, high-frequency sounds indicate appeasement or fear. Additionally, if a signal rises in frequency, whether it is harsh or tonal, it represents a decrease in hostility and an increase in appeasement or fear, whereas a signal that decreases in frequency represents an increase in hostility. Morton (1977) also proposed that most calls are structurally graded and are used in a variety of circumstances such that the specific message content of any particular signal can be reliably interpreted only with the aid of additional contextual information (Morton 1982).

There is general support for these motivation-structural rules of vocal communication. However, at the same time, additional research has demonstrated that, at least for some species, alarm calls may also convey more specific details of predator encounters (Marler 1985). For example, the structurally distinct alarm signals produced by vervet monkeys appear to track the category of predator encountered (i.e., eagle, leopard, snake). Given their apparent predator-specificity, such calls have been labeled “referential” because they appear to function as rudimentary symbols of the predators themselves akin to our human words for these animals. In order for a vocalization to be considered a referential signal, it needs to meet two specific criteria (Evans 1997): (1) it must be produced only in particular contexts, such as in encounters with a specific category of predator; (2) its effect on listeners must be context-independent in that the call alone must allow listeners to engage in appropriate responses without the need for contextual information (Macedonia and Evans 1993).

A number of primate and other mammalian taxa have been reported to produce alarm signals that meet these criteria for functional reference (Digweed et al. 2005; Greene and Meagher 1998; Kirchlof and Hammerschmidt 2006). The best-documented example comes from the alarm calls of vervet monkeys (Cheney and Seyfarth 1990). Vervet monkeys are small-bodied

monkeys that tend to move both on the ground and in the trees and are thus exposed to a wide variety of predators, including large cats, raptorial birds, and snakes. Observational and experimental research has shown that vervet monkeys produce three acoustically distinct alarm calls to these three different classes of predator, and that each predator induces a distinct behavioral response that is appropriate to it (Seyfarth et al. 1980). For example, upon spotting a leopard, vervets give one type of alarm call and immediately scramble up a tree and out onto its terminal branches where leopards are too large to go. On spotting an aerial predator, the monkeys give a different alarm call and immediately drop out of the tree where they are most vulnerable. On encountering a snake, the monkeys give a third alarm call type and stand bipedally to scan the ground around them. Importantly, animals that hear an alarm call engage the appropriate response even if they themselves have not actually seen the predator. Hence, the calls seem to “refer to” the predators in a way at least crudely similar to our own words for these animals (Seyfarth et al. 1980).

Subsequent research has documented a similar system of acoustically distinct, predator-specific alarm calls in a handful of other primate species including ring-tailed lemurs, Diana monkeys, and Campbell’s monkeys (Macedonia 1990; Zuberbühler 2000, 2001). The word-like properties of such alarm calls appears to be shared by domestic chickens, who produce two distinct alarm calls, one for ground predators and one for aerial predators (Evans et al. 1993). Upon seeing an aerial predator, or hearing an aerial predator alarm call, a chicken will turn an eye to the sky and/or crouch and run for cover. In contrast, when they spot a ground predator (e.g., raccoon) or hear the ground predator alarm call, chickens assume an erect vigilant posture as the prelude to rapid escape (running or flying away). Systematic experiments revealed that caged chickens produce an aerial alarm call when videos of eagles are shown from monitors positioned above their cages and produce terrestrial alarm calls to videotape of raccoons on a monitor positioned at ground level (Evans et al. 1993). Playback experiments revealed that the same responses were

elicited by playback of the alarm calls in the absence of any associated predator or model of it, suggesting that the behavioral responses do not require additional contextual information (Evans et al. 1993).

However, further experiments revealed that when video of a raccoon was presented from a monitor above the cage, the chickens produced the aerial alarm call and crouched low to the ground, behavior more appropriate to raptors flying overhead (Evans and Marler 1995). Similarly, when video of an eagle was played from a monitor positioned on the ground, the chickens gave the terrestrial predator alarm call and stood erect and vigilant, behavior more appropriate to a terrestrial predators encountered on the ground (Evans and Marler 1995). These findings suggest that the alarm calls and associated behavioral responses of chickens might be driven more by the position of the predator (in the air or on the ground) than by the class of predator per se.

At the same time, research on other primate and mammal species suggests that alarm calls do not necessarily represent the predators at all but instead reflect the relative urgency of response that is required (Fichtel and Kappeler 2002; Le Roux et al. 2001; Randall and Rogovin 2002). One of the clearest documented examples of these types of calls comes from California ground squirrels, *Spermophilus beecheyi*. Ground squirrels were found to produce “whistle” vocalizations primarily in response to large raptors and “chatter” vocalizations primarily in response to terrestrial predators (Owings and Leger 1980). On the surface, then, the calls appeared to represent the different predator types much the way the alarm vocalizations of vervet monkeys represent the different predators they encounter. However, additional research on California ground squirrels revealed additional important variation.

Ground squirrels typically produce a broadband “chatter” vocalization when they detect terrestrial predators at a distance and then stand bipedally to monitor the predator’s movements to see if they need to escape to their burrows. In contrast, when they spot an aerial predator, typically only at close range and stooping, the squirrels produce a high-frequency, tonal “whistle” and

bolt immediately for their burrows (Owings and Virginia 1978; Owings and Leger 1980). However, when a terrestrial predator is detected only at the last minute and at close range, the ground squirrels emit the tonal whistle and run immediately for their burrows, whereas, when a raptor is spotted in the distance, they emit the chatter call and remain vigilant to see what the raptor will do. As a result, although the whistle and chatter alarm calls correlate with the distinction between aerial and terrestrial predators, this correlation seems to reflect a coincidence in how these different predators are typically encountered because, ultimately, the production of the calls is most sensitive to the immediacy of the risk and therefore the urgency of response that is required independent of the type of predator involved (Owings and Morton 1998).

Alarm call systems in other species appear to reflect neither strictly referential categorizations of predator types nor response urgency. For example, white-faced capuchin monkeys (*Cebus capucinus*) of Central America produce two subtly distinct alarm calls, one given relatively exclusively to aerial predators and the other given to terrestrial predators but also produced in a range of other circumstances as well (Digweed et al. 2005). The loud bark call used in terrestrial predator encounters is sometimes also given to non-predatory species and can be used in broader mobbing contexts, such as when confronting and surrounding potential food competitors or species on which the capuchins themselves prey. It appears then that capuchins have a mixed system of alarm calling, with one call given fairly specifically to aerial predators and a subtly different call given in a wider range of contexts that involve threat or aggression on the part of the monkeys (Digweed et al. 2005).

Such mixed alarm call systems are not without precedent in primates. Paralleling the capuchins, saddleback tamarins (*Saguinus fuscicollis*) use the same call that they produce to terrestrial predators in other assertive contexts such as intergroup encounters (Kirchlof and Hammerschmidt 2006). Similarly, white sifakas (*Propithecus verreauxi*), a prosimian primate from Madagascar,

also display a mixed alarm call system (Fichtel and Kappeler 2002). Like capuchins, sifaka produce one call specifically for aerial predators and another for terrestrial predators and in other situations of high arousal, including aggressive interactions with conspecifics.

These mixed systems of calling may highlight other important ecological or social distinctions among species. For example, both the white sifaka and saddleback tamarin are almost exclusively arboreal and so, by definition, may have a more limited range of escape options and thus a less focused need for multiple predator-specific alarm messages (Fichtel and Kappeler 2002; Kirchlof and Hammerschmidt 2006). White-faced capuchins are semiarboreal and semiterrestrial and so, like vervet monkeys, have a diversity of possible escape responses to the various predators that prey on them. However, unlike vervet monkeys, capuchins are, as a species, more assertive and pugnacious generally. They are known to prey on other small mammals (e.g., coati pups) and birds, and they aggressively confront other fruit competitors (e.g., peccary). They also sometimes confront and mob potential predators like tayra and some snake species. Hence, their approach to many species may be more confrontational generally. As a result, they may have evolved a mixed alarm call system that can alert conspecifics to some specific dangers (e.g., stooping raptor) but that can also function more generally to attract others attention to the source of a disturbance, whether it is a predator or competitor, or even a potential prey animal, to facilitate active engagement or mobbing (Digweed et al. 2005).

In sum, there are a variety of possible functions for the alarm calls produced by prey species encountering predators and a similar variety of possible underlying mechanisms that motivate calling, and there is, as yet, no clear framework for predicting which will apply in a given species.

## Alex the Parrot

Irene M. Pepperberg  
Department of Psychology, Harvard University,  
Cambridge, MA, USA

## Synonyms

Animal “language”; Avian cognition; Comparative cognition; Nonhuman intelligence; Parrot cognition

Alex, a Grey parrot (*Psittacus erithacus*), was known for his extensive cognitive and communicative abilities. He was the subject of a 30-year research project to determine similarities and differences between his capacities and those of humans and various other nonhuman subjects. A description of his life and achievements follows.

## Early Life

Hand-raised by a Chicago area parrot breeder, Alex was sold to a local pet store at about 4 months of age, where he resided, in a large cage with other Grey parrots, until approximately 13 months of age. He was then chosen, at random by the store manager, to become a research subject. Random choice ensured that any experimental success was not a consequence of having been bred specifically for intelligence or vocal ability.

## Laboratory Environment

Although Alex was a research subject that lived in a laboratory setting at various universities (Purdue, Northwestern, University of Arizona, MIT, Brandeis), his environment was designed somewhat like that of a children’s preschool. He was caged only at night or if left alone temporarily during the day. He did not interact with other parrots during his first 14 years of research, but had constant human companionship. He was trained and tested at specific times; at other times he was simply treated as one might treat a young child: humans labeled objects with which he was interacting or foods he was eating, vocally noting their colors and shapes; humans asked him what he wanted or where he wished to go within the laboratory (options included his cage, a jungle gym, human shoulders, knees, etc.). He was never food- or water-deprived, although a delicacy might be withheld until he vocally labeled it.

## Training Techniques

Alex was trained by an interactive procedure, the Model/Rival (M/R) technique, based on methods developed by Bandura and Todt. Details and rationale for the procedure and full citations for these researchers are provided elsewhere (e.g., Pepperberg 1981, 1999). Briefly, the technique involves three-way *social* interactions among two humans and the parrot to demonstrate targeted vocal behaviors (Pepperberg 1981). The parrot watches and listens as one trainer presents objects and queries the other trainer about them (e.g., “What’s here?”, “What shape?”), giving praise and transferring the named object to the human partner to reward correct answers. Incorrect responses are punished by scolding and temporarily removing items from sight. Thus, the second human is both a model for the parrot’s responses and its rival for the trainer’s attention and illustrates consequences of errors. Eventually the parrot is included in interactions, being queried and rewarded for successive approximations to correct responses; training is adjusted to its performance level. The M/R technique exchanges

roles of trainer and model, so that the parrot learns that one person is never solely the questioner and the other the respondent, but that both individuals can undertake both parts in the interaction. Because the object is transferred upon its identification, as an intrinsic reinforcer, the bird experiences the direct link between object and label (Pepperberg 1981, 1983). Later, a bird is trained to state “I want X,” to separate requesting and labeling (Pepperberg 1988a) and to enable it to request preferred rewards while learning labels for items in which it has little interest.

## First Labels

Via M/R training, Alex first learned to vocally identify various materials and objects. After 26 months, his vocabulary consisted of nine nouns: paper, key, wood, hide (rawhide chips), peg wood (wooden clothes pins), cork, corn, nut, pasta (bow-tie macaroni); three color adjectives: rose (red), green, and blue; two shape phrases: three-corner (triangle) and four-corner (square); and functional use of the word “no” (Pepperberg 1981). He could identify materials and objects even if they differed from training exemplars (e.g., “wood” was identified correctly whatever the size, shape, or color). Given the various possible combinations of his labels, he could identify, spontaneously request, or refuse over 30 different items with an accuracy of ~80% (Pepperberg 1981). Of particular interest was that, without training, he transferred color and shape labels to items that constituted novel combinations of shape/color and material.

Alex also began acquiring labels without direct training. He learned something about the phonology of his labels – that new vocalizations to describe novel objects or those he particularly desired could be formed by recombining parts of existent utterances (e.g., “banerry” – banana/cherry – for an apple) or multiple labels (e.g., “grey nut” for a sunflower seed). For additional examples, see Pepperberg (1990b, 2009). He learned he could query trainers to acquire labels for novel items, colors, and materials, using phrases such as “What’s that?” or “What color?”

(Pepperberg 1990b). He engaged in considerable private vocal practice to refine such labels (Pepperberg et al. 1991). Details of such behavior can be found in the cited references and are summarized in Pepperberg (1999).

## Concept of Category

Such data led to an investigation of whether Alex could understand hierarchical concepts and their associated labels – that is, recognize not just what is or is not “green,” but that attributes such as “green” and “blue,” “3-corner” and “4-corner,” and “wood” and “paper” could be appropriately subsumed under specific, respective labels of “color,” “shape,” and “matter,” and that any object could be described in terms of any one or any combination of these attributes. For example, given a particular item, could he learn to respond “rose” to “What color?”, “4-corner” to “What shape?”, “wood” to “What matter?”, and “block” to “What toy?” (Pepperberg 1983). By this time, he had two more color labels (“yellow,” “grey” – charcoal to black) and two more shape labels (“2-corner,” “5-corner”). Initially, he successfully responded to color and shape queries, identifying different attributes of a single exemplar successively. Later, he learned to respond to “What matter/toy?” (Pepperberg 1999). Thus, he extracted the relevant category from a multivariant item, responding with the label for the one, correct instance of this category at better than 80% accuracy, even when combinations of color/shape/material were novel (Pepperberg 1983).

## Object Permanence

A subject, human or nonhuman, who understands object permanence knows objects do not cease to exist if they move out of view and that their physically distinct aspects are unaffected by movement (Piaget 1952). Although the concept seems so basic that no organism could exist without it, it develops over time and in several stages, each stage representing a different level of comprehension (Piaget 1952). Only after Piaget’s

writings were translated into English did researchers examine how nonhuman development might compare to that of humans, and, even then, most studies involved nonhuman primates (review in Doré and Dumas 1987).

The original object permanence study (Pepperberg and Kozak 1986) was based on the early experiments with nonhuman primates and children. Using those criteria, Alex succeeded on all stages. He could, for example, infer the transfer of a hidden object that could have been moved to any of three locations, and succeeded on a trick question in which the object's hiding place is not where it logically should be (Pepperberg and Kozak 1986). After researchers re-evaluated those earlier experiments, criteria for full Stage 6 object permanence became more stringent, but Alex, and later another Grey parrot, Griffin, succeeded on these additional tasks, including a variation of the carnival "shell game" (switching hiding places) and another ensuring that the subject was attending to the particular object being hidden by surreptitiously replacing it with a less-favored item (Pepperberg et al. 1997). Additional studies also confirmed that Grey parrots could not have been tracking olfactory cues or eye gaze (e.g., Pepperberg et al. 2013).

## Concepts of Same/Difference

Researchers once believed the concept of same/different could not be mastered by nonhumans other than primates (Premack 1983). Same/different involves not simply recognizing identity versus nonidentity, but rather understanding that any two items can have certain attributes in common (e.g., same color, shape) and others in which they differ (e.g., size, material), being able to designate these relationships via arbitrary symbols, and transferring this understanding to any novel exemplar set (Premack 1983). Demonstrating success by a nonprimate, non-mammalian subject would be an important scientific advance.

Alex already comprehended the concept of category; could he now use category labels in a

same/different task (Pepperberg 1987a) He learned, via M/R training, to answer queries of "What's same/different?" to a small subset of item pairs (sets that were red, green, or blue; triangular or square; and rawhide or wood) with the appropriate *category* label, "color," "shape," or "matter" (the latter pronounced "mah-mah"). To be correct, he had to (1) attend to multiple aspects of two different objects; (2) determine, from a vocal question, if his response should be based on similarity *or* difference; (3) determine, for the items shown, which categories were same and which were different (e.g., were both items triangular, or green, or of different material?); and (4) vocally encode the label for the targeted category. He was then tested on novel pairs, including objects whose attributes he could not label (e.g., a pink plastic elephant and a brown plastic toad). His accuracy averaged between 76% and 80% (Pepperberg 1987a). He responded equally well on "trick" questions, in which more than one attribute was either same or different; those trials ensured he was attending to the questions and not responding simply to the single odd attribute (Pepperberg 1987a).

## Concept of Absence

Experiments on the concept of nonexistence are difficult. Subjects generally respond to absence only when their expectation of presence is violated; furthermore, verbally encoding this situation (reacting in a specific manner) rather than, for example, simply avoiding stimuli that fail to provide rewards denotes a relatively advanced stage of cognitive development (Brown 1973). As of the early-1980s, only marine mammals (a sea lion, *Zalophus californianus*; a dolphin, *Tursiops truncatus*) and two chimpanzees (*Pan troglodytes*) had demonstrated such behavior (for full citations for these studies, see Pepperberg 1988b). What about a talking parrot?

Alex learned, using the M/R technique, to respond "none" to the *absence* of either similarity or difference between two objects (Pepperberg 1988b). As before, training occurred on a small

subset of items, and testing used novel items, usually involving attributes for which Alex had no labels. Accuracy averaged 80–84%, showing he was as knowledgeable as other nonhumans previously tested.

## Relational Concepts

The ability to respond to relational rather than absolute concepts is a frequently used metric for cross-species comparisons (see Premack 1983), because learning about relative concepts (e.g., “darker than”) is more difficult than learning about absolute concepts (e.g., “black”). Responding on a relative basis requires a subject to compare stimulus choices (e.g., grey is dark compared to white, light compared to black), then derive and use an underlying, more abstract, general concept; in contrast, learning an absolute stimulus value requires forming a single association (e.g., label “X” to designate x). Could Alex understand a relative concept?

Relative size was chosen (Pepperberg and Brezinsky 1991). Alex learned to respond to “What color bigger/smaller?” for a small subset of items. Using both queries meant that, as in previous tasks, he had to attend closely to the question and not simply respond based on, for example, “more.” Testing again involved many novel combinations of many novel items, for which he often had no labels. His accuracy was >77% (Pepperberg and Brezinsky 1991). Notably, without any training, he transferred use of “none” from absence of similarity/difference to an absence of a size differential, a totally distinct attribute: When first shown exemplars of the same size, he spontaneously responded “none.” He also, without training, correctly responded to “What *matter* bigger/smaller?” (Pepperberg and Brezinsky 1991).

## Comprehension Studies

Alex produced labels on demand and vocally requested information, but label comprehension had not formally been examined. Such testing was

necessary: Studies with apes had shown they could have good production skills without comprehension and vice versa (Savage-Rumbaugh 1986).

Without additional training, two experiments were performed. First, Alex saw groupings of multiple objects of various colors, shapes, and materials and was asked about a specific attribute (e.g., “What color is object-X?”, “What shape is object-Y?”, “What object is color-A?”, or “What object is shape-B?”). Accuracy was >80% for all queries (Pepperberg 1990a). Next, he was required to label the specific instance of one category of an item uniquely defined by the *conjunction* of two other categories (e.g., “What color is shape-A *and* object/material-B?”). Other items in the collection exemplified one, but not both, these defining categories. Accuracy was >76% (Pepperberg 1992). Given that he could succeed only if he understood the targets of all these questions, his data demonstrate equivalent comprehension and production abilities (for the implications of these findings, see Pepperberg 1999).

## Basic Number Concepts

Koehler’s earlier studies on Grey parrots (for a review, see Pepperberg 1999) demonstrated that these birds could perform complex match-to-sample tasks involving number, and had ruled out alternative explanations based on mass, contour, density, brightness, etc. But whether a non-human could actually *count*, in the same manner as young children (reviewed in Pepperberg and Carey 2012) was a different matter (see Pepperberg 2006a). Alex’s numerical experiments spanned the 1980s until his death in 2007.

Because Alex already knew the labels “three” and “four” (see above), M/R training began on collections of three and four objects, using a subset of items he could label; testing (i.e., “How many?”) involved a wide range of novel sets. He was subsequently trained on “two” and “five,” then “six” and “one.” When tested on novel sets for all numbers including sets of objects he could not label, placed in completely random arrays,

accuracy was 75–80%; tests controlled for all nonnumerical bases for his responses (Pepperberg 1987b). Notably, he represented quantities exactly – error patterns were random, not showing the peak near correct responses that would suggest only a general sense of quantity. The majority of errors were generic – labeling a set of keys as “key,” not “three key.” Such responses were not completely wrong, but Alex had not answered the question; thus, these responses were considered errors. Without training, he also labeled the quantity of a subset of objects within a grouping (e.g., Xs among Xs and Ys) with 70% accuracy, something young children find difficult (reviewed in Pepperberg 1999).

These data demonstrated that Alex could quantify sets, but did not specify the mechanism being used. Adult humans achieve similar numerical accuracy on such tasks either by subitizing or clumping – perceptual, not counting, mechanisms. Subitizing and clumping are used for small sets when sufficient time for counting is unavailable (see Pepperberg 1999). Thus, Alex was, without training, given an additional task involving heterogeneous sets, developed for humans, to separate counting from other mechanisms. He was asked about the quantity of a subset in a complex grouping – e.g., how many red blocks in a set of red and blue balls and blocks (Pepperberg 1994). On such a task, humans count, even when the answer involves a single item. Alex’s accuracy, >80%, matched that of humans, suggesting a counting strategy. However, avian perceptual capacities might be more advanced than those of humans. Thus, a noncounting mechanism could not be ruled out, but the decision was made to study other numerical abilities first.

Alex was also tested on comprehension of numerical labels. In a variant of the heterogeneous subset task, he saw collections involving random arrays of several numerical subsets of different colors (e.g., sets of keys, four red, five green, and six blue) or objects (e.g., all blue items, two key, three cork, five block) and, without any training, was asked to label the color of a particular number (e.g., respectively, “What color six?”, “What object three?”; Pepperberg and Gordon 2005). Accuracy was ~88%.

## A Zero-Like Concept

Unexpectedly, during the comprehension study, Alex spontaneously used “none” to represent absence of a set of a targeted quantity: a zero-like concept. Shown a set of two, three, and six objects, he was asked “What color three?” Instead of providing a color, he said “five.” He repeated “five” when asked twice more. He did not display disruptive behavior patterns that sometimes indicated a disinclination to work on a given task (e.g., Pepperberg and Gordon 2005), just continued replying “five.” The questioner, realizing something unusual, said “OK, Alex, tell me, what color five?”; he immediately responded “none” – thus, without training, transferring the concept from absence of an attribute (“same/different”) to absence of quantity (Pepperberg and Gordon 2005). Further testing demonstrated this was not a chance occurrence. He had, additionally, manipulated the trainer into asking the question he wished to answer, demonstrating some level of intentionality. His use of “none” was not equivalent to a human’s use of “zero,” but clearly an important step.

## Addition

Alex spontaneously showed an interest in addition, during training of the aforementioned Griffin on sequential auditory number processing (Pepperberg 2006a). True addition is complex and rare among nonhumans: For example, only one study, on an ape (chimpanzee), involved summation and required that the animal symbolically label the sum up to four (Boysen and Berntson 1989). Other studies purporting to test addition either did not require symbolic labeling or the subjects could be responding with respect to non-numeric bases (e.g., density, mass, contour; see Pepperberg 2006a). Thus, when Alex seemingly labeled the total number of clicks presented to Griffin over separate trials, the decision was made to investigate his abilities formally.

The study adapted the protocol of Boysen and Berntson (1989). Alex saw a tray with two upside down cups, under which trainers had earlier

hidden various quantities of differently sized items such as nut pieces, cracker bits, or jelly beans. Identical candy hearts were occasionally used to see if accuracy was higher when mass/contour cues were available. An experimenter brought the tray to Alex's face, lifted the left cup, showed what it hid for 2–3 s in initial trials, replaced the cup over the quantity, then replicated the procedure for the right cup (Pepperberg 2006a); Alex was asked "How many total?" On some trials, nothing was under both cups to see if he could transfer use of "none" to this situation; for other trials, sets contained from one to six items, in all possible combinations. Overall, accuracy was ~85%; however, as the data came in, it became clear that Alex seemed to have specific difficulty with trials involving five objects under one cup and nothing under the other, stating "six" (his largest number at the time). Such results suggested that, like humans, he might be subitizing – using a fast perceptual mechanism – when he did not have enough time actually to count. Thus, the time during which the sets were visible was increased; his accuracy on  $5 + 0$  went to 100% (Pepperberg 2006a). Data from these experiments not only demonstrated Alex's competence in addition, but also presented evidence for a counting-like strategy for the quantity five. Interestingly, he did not use "none" at a statistically significant level when it would have been appropriate, showing that his concept of zero, closely related to absence, was not as fully developed as that of humans (Pepperberg 2006a). However, he never stated "two" – the number of cups – for zero; thus, he realized what was to be enumerated. He often stated "one," somewhat like another chimpanzee, Ai (Biro and Matsuzawa 2001), also trained on numerical symbols, who confused "one" and "zero" and seemed to understand that both labels represented quantities at the lower end of the number line.

Later, two complex forms of summation were tested. First, Alex was required to sum over three object sets with a maximum total value of six (Pepperberg 2012). Three sets would likely require additional memory load, requiring two updates after seeing the first set rather than one update. His death precluded testing all possible

addends and sums, but he scored a statistically significant 8/10 on trials that were possible. Because he had by then (see below) learned the meanings of Arabic numerals and quantities to eight (Pepperberg and Carey 2012), a second experiment tested his ability to add two Arabic numerals to maximum value of eight. To be correct, he would have to understand the exact, not an approximate, meaning of the Arabic symbols. Again, his death precluded all possible combinations, but he achieved a statistically significant score of 9/12 (Pepperberg 2012). His data suggested abilities somewhat more advanced than those of chimpanzees (Boysen and Berntson 1989).

## Ordinality and Equivalence

Alex's "one"/"none" confusion when asked about absence of a set of objects would make sense if he grouped one/zero as quantifying the smallest amounts he could label; such grouping would also suggest some understanding of the order of his number labels. Were that the case, he would have made the inference on his own, because – as noted above – his numerical labels were not trained in order, as occurs for children (see Pepperberg and Carey 2012). Interestingly, apes, like those described above that symbolically label quantities, never inferred ordinality of all their numbers – that is, never inferred a full number line, in which each number is one more than the one before and one less than the one after. Unlike young children, they had to undergo extensive training to acquire such understanding (e.g., Biro and Matsuzawa 2001; Boysen et al. 1993; see discussion in Pepperberg 2006b). Might Alex have inferred ordinal relations among all his numerals on his own?

To test this possibility, he was first trained to label Arabic numerals in the absence of quantities to which they referred (Pepperberg 2006b). He saw trays of differently colored numerals, colors of each numeral varying among the trials, and via M/R training, learned to respond to, for example, "What color six?" or "What number blue?" He thereby acquired both production and

comprehension of the relationships between Arabic numerals and his vocal labels; he already comprehended and produced the same vocal labels in conjunction with object sets. If, based on the relationships between object sets and vocal labels, and vocal labels and numerals, he could infer equivalence relationships between the Arabic numerals and sets, testing on such inferences could provide information about ordinality: He could be given two Arabic numerals and, given his knowledge of bigger/smaller (Pepperberg and Brezinsky 1991), could be asked which was bigger or smaller. He could succeed only if he understood both the equivalence relationship and ordinality. To allow multiple queries on the same pairs without engaging in training, different colors of Arabic numerals were used; he was queried “What color number bigger/smaller?” (Pepperberg 2006b). Numerals of same value and physical size but different colors were also used to see if he replied “none”; numerals of the same value but different colors and physical sizes were used to see if he also replied “none”; and Arabic numerals were compared with sets of objects that were smaller or larger than the numeral’s value to evaluate the extent of his knowledge (Pepperberg 2006b). All such trials were intermixed.

He succeeded on every comparison involving two same-sized Arabic numerals, including those involving “none,” averaging 83–88%. For trials on Arabic numerals of the same value, but of different sizes, counting as correct either “none” or the color label of the targeted number (because the basis for his response was the issue of interest, either size or value would be correct), his accuracy was 100% (chance of 2/3: a color or “none”). Interestingly, he began these trials responding based on which numeral was physically bigger, but halfway through the study switched to saying “none,” likely transferring his understanding that the task was based on symbolic value from the other trials (Pepperberg 2006b).

For trials contrasting Arabic numerals with object sets, with one exception he was correct whether sets represented values greater or smaller than the numeral (e.g., given an orange Arabic 6 and three blue blocks and asked “What color

bigger?”, he responded “orange”). The sole exception was for sets containing *one* object and an Arabic numeral – then he consistently responded “none,” as though the question referred only to the number of objects and not symbolic values (Pepperberg 2006b).

Responses demonstrated that he inferred not only the equivalence of numerosity of Arabic numerals, vocal labels, and object sets, but also the ordinality of his numerical symbols. Thus, he responded more like children than other non-human subjects (see Pepperberg 2006b).

### Could Alex’s Number Sense Resemble Children’s Even Further?

Although these studies demonstrated numerical competence beyond that of other nonhumans, Alex still differed from children (reviewed in Pepperberg and Carey 2012). For example, children acquire an understanding of numbers below 4 by training and above 4 by inference: They learn cardinality (the value of numerical symbols) for very small numbers ( $<4$ ) and a general sense of “more versus less” while acquiring a meaningless, rote ordinal number series (much like they initially learn the alphabet, without understanding that “LMNOP” represents several letters), usually roughly between ages 2 and 4 years. At about 4 years, they associate knowledge of quantity in the small sets with this number sequence to form 1:1 correspondences that they extend to larger amounts for both cardinal and ordinal accuracy (reviewed in Pepperberg and Carey 2012). Children thereby generally deduce meaning for numerals “five” and above without any training. No nonhuman, including Alex, demonstrated this type of inference. But Alex had inferred ordinality; why not cardinality?

Some evidence suggested that Alex’s difficulty in acquiring new labels might depend more on learning how to physically produce their sounds than with learning their meanings (see Pepperberg 1999). To produce any given English utterance, he had to learn to coordinate his syrinx, tracheal muscles, glottis, larynx, tongue height and protrusion, beak opening, and even his esophagus

(reviewed in Pepperberg 1999). A plan was devised to separate issues of vocal production from those of numerical label comprehension (Pepperberg and Carey 2012).

The plan had several steps. First, Alex was tested on sets containing numbers of items beyond his current labeling ability: Would he use “six,” his largest current label, or somehow indicate that these sets did not correspond to number labels he could produce? He reacted as if the latter: He refused to answer unless badgered multiple times with the same question (Pepperberg and Carey 2012). He was also asked to identify the color of a set of six items on trays containing, for example, sets of four, seven, and eight items; here he replied “none,” again showing he did not label the color of the closest, but incorrect, set (Pepperberg and Carey 2012).

The labels 7 and 8 were trained in the absence of appropriate sets of objects. Alex had no knowledge that they were even numbers at this stage; thus, he was also trained that  $6 < 7 < 8$ . He was then tested as to whether he could infer the relationships among 7, 8, and his other Arabic symbols. He succeeded, but that did not yet show he understood exact meanings for 7, 8 – which could, for example, represent 10 and 20 items.

The final test involved presenting sets of seven and eight items and asking “How many?” to see if Alex would use his novel labels appropriately on first trials. As he had been trained on two novel labels, he could not simply infer a relation between a novel label and a novel set. But because his earlier labels had been taught in pairs that were one larger and one smaller than his current knowledge (i.e., training on “two” and “five” after testing “three” and “four”), and he already knew “none” was the only label to indicate something less than “one,” and “eight” was larger than “seven,” he likely had a good chance of success. He did succeed, showing he, like children, understood that, without specific training, “eight” was exactly one more than “seven,” which was exactly one more than “six”: that is, he could infer cardinality from ordinality (Pepperberg and Carey 2012). Thus, despite being phylogenetically much further from humans than are great apes, he responded more like children than did the apes.

## Optical Illusions

Alex was also evaluated on how he literally saw the world – how he processed the Müller-Lyer optical illusion, for which humans either underestimate or overestimate the length of a line with arrows attached, respectively, either inwardly  $< >$  or outwardly  $> <$  (Pepperberg et al. 2008). Using the Brentano version in which the two figures are fused (see figures in Pepperberg et al. 2008) and two differently colored lines, without training Alex was asked “What color bigger/smaller?” (Pepperberg and Brezinsky 1991). Perpendicular lines instead of arrows were used on some trials, to see if he would respond “none” (i.e., nothing bigger nor smaller) when humans would not see any illusion. Arrow angles more acute or obtuse, and central lines thicker or thinner than in the original stimuli, were used to see if Alex reacted as do humans when certain aspects of the figure are emphasized or de-emphasized. He reported the illusion in trials where human observers would have reported the classic illusion and he showed a lessened or absent illusion in trials where humans would not have reported the illusion or were less likely to do so because of variations in line width or arrow angle (Figs. 4 and 5 in Pepperberg et al. 2008). The data were particularly interesting in that tests did not use statistical averaging over hundreds of trials, nor did training involve related figures as was generally the case for other nonhumans; Alex’s vocal responses were simply recorded.

## Conclusion

Alex died September 6, 2007; he had lived for 31 years, spending 30 of them among humans dedicated to demonstrating the extent of his cognitive and communicative abilities. He was the first nonhuman, nonprimate, nonmammalian subject to acquire elements of a human communication system, and the only one to learn to do so via human speech. Use of symbolic representation enabled him to learn advanced concepts and be compared with other nonhumans with similar

capacities; his vocal abilities allowed him to be questioned the same way as young children, so direct comparisons could be made with humans. His data led to a breakthrough in understanding avian capacities and inspired studies on large numbers of psittacine and corvid species. Although his early demise meant his understanding of many other concepts were not tested, research has continued with several Grey parrots.

## Algae

Suman Yadav  
Department of Botany, Institute of Science,  
Banaras Hindu University, Varanasi, UP, India

### Definition

It is an assemblage of photosynthetic aquatic protists including seaweeds and other unicellular forms containing chlorophyll and lack stem roots and leaves.

### Introduction

The algae are photosynthetic thallophytes (plant lacking root stem and leaves) having chlorophyll as a primary photosynthetic pigment and lack a sterile covering of cells around the reproductive

cells. Together with the other land plants, in aquatic ecosystem the algae by photosynthesis play major role in the global primary production. The algae are found in enormous range of habitats, more commonly occur in water both in fresh and marine, from snowfields to the hot spring and from damp earth and plant leaves to sun baked desert soil. Some endolithic algae colonize in the cracks of rocks. It can also occur on shores and coasts, attached to the bottom or live suspended in the water itself. Algae play a very important role in carbon cycle as it is primary producer and the environment has free oxygen due to presence of algae and cyanobacteria. They help in living by producing oxygen in one way, but in other way, their enormous growth causes algal boom in water body that may be detrimental to other aquatic body like fishes. Algae are considered as a polyphyletic group because they do not have a common ancestor (Nabors 2004). They show a wide range of reproduction from simple asexual to complex sexual (Smithsonian 2010). Many structures that significantly present in the land plant like phyllids of bryophytes; roots, leaves, and other organs found in tracheophytes (vascular plants); and rhizoids in nonvascular plant are lacking in algae. Most of the algae are phototrophic and mixotrophic, i.e., deriving energy both from photosynthesis and uptake of organic carbon either by osmotrophy, myzotrophy, or phagotrophy. Some of the unicellular species of green algae, dinoflagellates, golden algae, and some others are heterotrophs or become parasites, relying entirely on external energy sources, and have limited or no photosynthetic apparatus (Figueroa-Martinez et al. 2015). The algae that have photosynthetic machinery is derived from cyanobacteria that produce oxygen as a by-product of photosynthesis, unlike other photosynthetic bacteria such as purple and green sulfur bacteria.

### Classification of Algae

The algae is classified in many ways

- Nuclear organization. It can be prokaryotic or eukaryotic. In prokaryotes there is only one class, i.e., cyanophyceae, whereas all other classes of algae come under eukaryote.
- Nature of cell wall components: The algal cell wall is generally made up of polysaccharide, lipid, and protein. The inner layer is made up of cellulose and the outer is pectin. In chlorophyceae, the cell wall is made up of cellulose. In phaeophyceae, cell wall contains alginic acid and fucinic acid. In rhodophyceae, the cell wall is made up of xylans and galactans.
- Pigmentation and photosynthetic apparatus: There are various pigments present in algae. Chlorophyll a is present in all algae, chlorophyll b is mainly present in chlorophyceae and eugleniacea, chlorophyll c is present in phaeophyceae and cryptophyceae, chlorophyll d is found in rhodophyceae, and chlorophyll e is found in xanthophyceae. Carotenoids are found in all classes of algae, and biliproteins are specially found in rhodophyceae and cyanophyceae.
- Nature of reserve food: Starch is the main reserve food in algae which is common in all classes. In rhodophyceae, the reserve food is floridean starch, in phaeophyceae the reserve food is laminarin.
- Flagellation: The number, types, and position of flagella also play important role for separation of different classes of algae. In cyanophyceae and rhodophyceae, the flagella are completely absent in vegetative and reproductive structure. All other classes have flagella in different orientation.
- Types of life cycle and reproduction: The presence and method of sexual reproduction are also important criteria for classification of algae.

F. E. Fritsch (1948) was the first to propose a most comprehensive and authoritative classification of algae. Fritsch has described in his book *The Structure and Reproduction of the Algae*.

### 1. Chlorophyceae

It is divided into nine orders

- (i) Volvocales, e.g., *Chlamydomonas*
  - (i) Chlorococcales, e.g., *Chlorella*, *Hydrodictyon*
  - (ii) Ulotrichales, e.g., *Ulothrix*
  - (iii) Cladophorales, e.g., *Cladophora*, *Pithophora*
  - (iv) Chaetophorales, e.g., *Ulvella*, *Coleochaete*
  - (v) Oedogoniales, e.g., *Oedogonium*
  - (vi) Conjugales, e.g., *Spirogyra*, *Zygnema*
  - (vii) Siphonales, e.g., *Vaucheria*
  - (viii) Charales, e.g., *Chara*, *Nitella*
2. **Xanthophyceae (Yellow green algae)**  
It is divided into four orders
- (i) Heterochloridales, e.g., *Heterochloris*
  - (ii) Heterococcales, e.g., *Myxochloris*
  - (iii) Heterotrichales, e.g., *Microspora*
  - (iv) Heterosiphonales, e.g., *Botrydium*
3. **Chrysophyceae**
- (ii) Chrysomonadales, e.g., *Crysodendron*
  - (iii) Chrysosphaerales, e.g., *Chrysosphaera*
  - (iv) Chrysotrichales, e.g., *Chrysoclonium*
4. **Bacillariophyceae (Diatom, yellow or golden brown algae)**
- (i) Centrales, e.g., *Chaetoceras*, *Cyclotella*
  - (ii) Pennales, e.g., *Pinnularia*, *Denticula*
5. **Cryptophyceae**
- (i) Cryptomonadales, e.g., *Cryptomonas*, *Cyanomonas*
  - (ii) Cryptococcales, e.g., *Tetragonidium*
6. **Dinophyceae**
- (i) Desmomonadales, e.g., *Desmocapsa*, *Desmomastrix*
  - (ii) Thecatales, e.g., *Prorocentrum*, *Exuviaella*
  - (iii) Dinophysiales, e.g., *Dinophysis*, *Phalacroma*
  - (iv) Dinoflagellata, e.g., *Elastodinium*, *Heterocapsa*
  - (v) Dinococcales, e.g., *Dinastridium*, *Dissodinium*
  - (vi) Dinotrichales, e.g., *Dinotrix*, *Dinoclonium*
7. **Chloromonadineae**
- (i) Chloromonadales, e.g., *Vacuolaria*, *Trentonia*
8. **Euglenoinaceae**
- (i) Euglenaceae, e.g., *Euglena*, *Ascoglena*

- (ii) Astasiaceae, e.g., *Astasia*, *Menoidium*
- (iii) Peranemaceae, e.g., *Petalomonas*, *Anisonema*

#### 9. Phaeophyceae

- (i) Ectocarpales, e.g., *Ectocarpus*, *Punctaria*
- (ii) Tilopteridales, e.g., *Tilopteris*
- (iii) Cuteriales, e.g., *Cutleria*
- (iv) Sporochneales, e.g., *Carpomitra*, *Sporochneus*
- (v) Desmarestiales, e.g., *Desmarestia*
- (vi) Laminariales, e.g., *Laminaria*, *Macrocystis*
- (vii) Sphacelariales, e.g., *Sphacelaria*
- (viii) Dictyotales, e.g., *Dictyota*, *Padina*
- (ix) Fucales, e.g., *Fucus*, *Sargassum*

#### 10. Rhodophyceae

- (i) Bangiales, e.g., *Bangia*, *Porphyra*
- (ii) Nemalionales, e.g., *Nemalion*, *Naccaria*
- (iii) Gelidiales, e.g., *Gelidium*
- (iv) Cryptonemiales, e.g., *Gloeopeltis*, *Dumontia*
- (v) Gigartinales, e.g., *Gigartina*, *Gracilaria*
- (vi) Rhodymeniales, e.g., *Rhodymenia*, *Champia*
- (vii) Ceramiales, e.g., *Polysiphonia*, *Ceramium*

#### 11. Myxophyceae

- (i) Chroococcales, e.g., *Gloeocapsa*, *Chroococcus*
- (ii) Chamaesiphonales, e.g., *Chamaesiphon*
- (iii) Pleurocapsales, e.g., *Pleurocapsa*
- (iv) Nostocales, e.g., *Nostoc*, *Oscillatoria*
- (v) Stigonematales, e.g., *Nostochopsis*, *Stigonema*

In 1989 Robert Edward Lee classified the algae into four distinct groups (Lee 2008).

**Group 1:** Prokaryotic algae – Cyanobacteria, chlorophyll *a*, phycobiliproteins.

**Group 2:** Eukaryotic algae with chloroplast surrounded by two membranes of the envelope.

**Glaucophyta:** It represents the intermediate position in the evolution of chloroplast.

**Rhodophyta:** No flagellated cells, floridean starch is storage product, chl *a*, phycobiliproteins.

**Chlorophyta:** Chlorophyll *a* and *b*, storage product is starch.

**Group 3:** Eukaryotic algae with chloroplast surrounded by one membrane of chloroplast endoplasmic reticulum.

Euglenophyta: Chlorophyll *a* and *b*, storage product is paramylon, characteristic type of cell division.

Dynophyta: (Dinoflagellates), mesokaryotic nucleus, chlorophyll *a* and *c<sub>1</sub>*, cell commonly divided into epicone and hypocone by a girdle, helical transverse flagellum.

Apicomplexa: Heterotrophic flagellates with colorless plastid.

**Group 4:** Eukaryotic algae with chloroplast surrounded by two membranes of chloroplast endoplasmic reticulum.

Cryptophyta: Nucleomorph present between inner and outer membrane of chloroplast endoplasmic reticulum, chlorophyll *a* and *c*, phycobiliprotein, periblast inside plasma membrane.

Heterokontophyta: Anterior tinsel and posterior whiplash type flagella, chlorophyll *a* and *c*, fucoxanthin, storage product is chrysolaminarin. The following classes have been identified (Anderson 2004).

Chrysophyceae (Golden brown algae): Chlorophylls *a*, *c<sub>1</sub>*, *c<sub>2</sub>* (Andersen and Mulkey 1983), two flagella perpendicular to each other.

Synurophyceae: Chlorophyll *a* and *c<sub>1</sub>*.

Eustigmatophyceae: Basal swelling of the tinsel flagellum adjacent to the eyespot, chlorophyll *a*.

Pinguiphyceae: Unusually high concentration of polyunsaturated acids, especially 20:5.

Dictyochophyceae: Tentacles or rhizopodial on basically amoeboid vegetative cells (Moestrup 1995; Preisig 1995).

Pelagophyceae: Unicellular algae.

Bolidophyceae is small order of flagellated marine picophytoplankton which is related to the diatoms and their cells have chlorophyll *a*, *c<sub>1</sub>*, *c<sub>2</sub>*, *c<sub>3</sub>*, beta-carotene, diatoxanthin, and fucoxanthin as do the diatoms.

Bacillariophyceae: Chlorophyll *a*, *c<sub>1</sub>*, and *c<sub>2</sub>* with the major carotenoid being the golden brown fucoxanthin.

**Raphidophyceae:** Chlorophyll *a* and *c*, two membranes of chloroplast endoplasmic reticulum, anterior flagellum is commonly tinsel, whereas the posterior flagellum is naked.

**Xanthophyceae:** Motile cells with a forwardly directed tinsel flagellum and a posteriorly directed whiplash flagellum, chlorophyll *a* and *c* (Sullivan et al. 1990).

**Phaeothamniophyceae:** Fucoxanthin and heteroxanthin occur together.

**Phaeophyceae:** Chlorophyll *a*, *c*<sub>1</sub>, and *c*<sub>2</sub>. Storage product is laminarin, exclusively found in marine habitat.

**Prymnesiophyta:** Uninucleate flagellate characterized by the presence of a haptonema between two smooth flagella.

## Algae and the Fossil Record

Fossilized filamentous algae from the Vindhya basin have been dated back to 1.6–1.7 billion years ago (Bengtson et al. 2009). The cyanobacteria in the form of stromatolites are the oldest group of algae dating back about 2700 million years. Earlier the atmosphere was devoid of oxygen and only composed of methane, ammonia, and other reduced compound. Photosynthesis by cyanobacteria started to build up the oxygen content of the atmosphere to what it is today. First eukaryotic algae appear was similar to Glaucophyta, with endosymbiotic cyanobacteria instead of chloroplasts.

## Symbiotic Algae

**Coral reefs** – These are deposition of calcareous exoskeleton of marine invertebrates of the order Sclerectinia. For cell building processes these cells metabolize sugar and oxygen and utilize the energy. The algal protists act as endosymbionts in the cells of the coral forming marine invertebrates and help them by generating sugar and oxygen available through photosynthesis using incident light and carbon dioxide produced by the host. Stony corals require endosymbiotic

algae from the genus *Symbiodinium* to be in a healthy condition (Taylor 1983).

**Sponges** – Some endosymbiotic algae live very close to the sponges like breadcrumb sponges (*Halichondria panicea*).

**Lichens** – It is the body structure formed by association of algae and fungi. The fungal symbiont belongs to ascomycotina or basidiomycotina, and the algal symbiont belongs to green algae and cyanobacteria. The association is termed a morphogenesis because the lichen has the form and capabilities not possessed by the symbiont species alone (they can be experimentally isolated).

## Algae and the Environment

**Toxic algae:** It can be toxic in two ways (Hallegraeff et al. 2003).

**Enormous populations in the aquatic environment:** Heavy growth of few algae, e.g., the diatom *Chaetoceros* or the prymnesiophyte *Chrysochromulina* can block the gills of fish and can be particularly a problem in aquaculture systems. Anoxxygenic condition created leads to killing of fish, at the end of blooms of other algae (e.g., green algae) as the algae die and decompose.

**Toxin production:** Some toxins produced by the algae kill other organisms that prey on these algae. Indeed, this probably was the reason that these algae were selected for in the evolutionary process since it reduced predation by grazers (Gilbert 1996). Filter-feeding shellfish can accumulate large quantities of these toxins as they filter the algae out of the water. Consumption of the shellfish by man, birds, and animals results in sickness and death. The algae that produce phycotoxins are:

### Cyanophyceae

**Neurotoxin and Saxitoxin:** It blocks the transmission of signal from neuron to neuron. These compounds bind to voltage activated Na<sup>+</sup> channels and block influx of Na<sup>+</sup>, thereby stopping the generation of an action potential (Shimizu 2000).

**Hepatotoxins:** Microcystin and nodularin are inhibitors of protein phosphatases.

## Chemical Defense Mechanisms of Algae

Loss of various micro- and macroalgal biomass occur by invertebrate predation and herbivore grazing. So, the algal population have evolved the chemical defense mechanism which can be constitutive or inducible. The toxic “red tide” dinoflagellates that have reduced grazing by copepods is the example of constitutive defense mechanism (Wolfe 2000). The increased production of phlorotannins by brown algae and the increased production of halogenated furones by red algae, on grazing by invertebrates, are examples of inducible defense mechanism (Pavia et al. 2003). Various types of defense chemicals are given below.

**Seriochemicals** – act between individual of the same species, e.g., pheromones

**Allelochemicals** – act between members of different species, e.g., kairomones and synomones (Cembella 2003)

**Bioremediation-** *Desmodesmus pleiomorphus* has been reported for biosorption of cadmium (Monteiro et al. 2010). *Fucus spiralis*, *Ascophyllum nodosum*, and *Chondrus crispus* are macroalgal species for copper sorption reported by Romera et al. (2007).

**Pollution control** – Some scientist found that 60–90% of nitrogen runoff and 70–100% phosphorus runoff is captured from manure effluents using a horizontal algae scrubber also known as algal turf scrubber (ATS). They found that cucumber and corn seedlings grew just as well using ATS organic fertilizer as they did with commercial fertilizers.

**Algal Sunscreen for ultraviolet damage** – Ozone depletion causes ultraviolet light to reach the earth that lead to hazardous consequences. Springtime ozone reductions up to 60% compared with values 30 years ago have been recorded (Karsten et al. 1999). This has resulted in increased amounts of UV-B reaching the surface of the earth. The production of ultraviolet sunscreen by algae is the one way the cells have evolved in dealing with damaging UV light. Most commonly used compound is Mycosporin like amino acid that absorbs between 310 and 360 nm (Karsten et al. 1999).

## Hydrogen Fuel Cells and Gas Production by Algae

Hydrogen fuel cells are clean energy source for vehicle nowadays and play a very important role in pollution control. The production of hydrogen gas in green algae has been extensively studied (Melis et al. 2000; Ghiradi et al. 2000). Nearly 40,000 algal species have been described, and this is likely only a small fraction of the total number of available species. The US Department of Energy’s Aquatic Species Program analyzed approximately 3000 different microalgae for their potential to produce biofuels (Kars et al. 2006).

## Conclusion

Algae is a group of morphologically diverse photosynthetic protists that live freely and in symbiotic relation with some organisms. It has various uses and applications including energy, biofuel production, and as various foods. Algae have some role in bioremediation and pollution control and also have chemical defense mechanism that protects them from invertebrate predation and herbivore grazing.

## Alkaloid

Neelabh

Department of Biotechnology, SR Institute of Management and Technology, Lucknow, Uttar Pradesh, India

Department of Zoology (MMV), Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

Alkaloids are cyclic compounds containing nitrogen in a negative oxidation state which is of limited distribution in a living organism. The term “alkaloid” marks its origin from the word “alkaline” which in Arabic means “ashes of plants.” They are generally known to be plant metabolites but are also produced by bacteria, fungi, and animals (Clark and Hufford 1992). Presently, more than 5,500 alkaloids are known and are highly placed with respect to their diversity, efficiency, and therapeutic significance. Research shows that almost 20% of the plants produce alkaloids and their major source in the flowering plants is the

angiosperm (Pelletier 1983). Being toxic in nature, their main role in plants is to defend them against the micro-organisms, insects, and herbivores.

Chemically, they are a class of natural compounds, majority of which contain nitrogen and a few of them being non-nitrogen heterocyclic organic amines. Mostly, basic in nature but these compounds can also range from being neutral to weakly acidic (McNaught and Wilkinson 1997). Apart from the usual carbon, hydrogen, and nitrogen, elements such as chlorine, oxygen, sulfur, phosphorous, and bromine might also exist in the alkaloids (Manske and Holmes 2014; Lewis 1998). Owing to their basic nature, they form alkaline solutions on dissolving in water and also form salts with acids. They are colorless, crystalline/liquid at room temperatures and have a bitter taste.

Attributable to the great structural diversity in the alkaloids, no fixed and uniform classification of the alkaloids exists. However, scientists most commonly divide the alkaloids into 5 classes:

- (a) **True alkaloids:** They owe their origin to the amino acids. The characteristic feature includes the presence of nitrogen in the heterocyclic ring. Some of the examples of this class include atropine, nicotine, and morphine (Plemenkov 2001).
- (b) **Protoalkaloids:** Like true alkaloids, protoalkaloids also originate from the amino acids but contain nitrogen which is not a part of the heterocyclic ring, e.g., mescaline, adrenaline, and ephedrine (Plemenkov 2001).
- (c) **Polyamine alkaloids:** Polyamine alkaloids are the derivatives of putrescine, spermidine, and spermine (Bienz et al. 2005).
- (d) **Cyclopeptide alkaloids:** They are macrocyclic compounds embodying ANSA (Ammonium N-phenyl-1-naphthylamine-8-sulfonate) structure. Further, they are most commonly present in Rhamnaceae family, e.g., mucronine and sativanine (Gournelis et al. 1997; Tuentner et al. 2017).
- (e) **Pseudoalkaloids:** They are pharmacologically active compounds which have not been derived from amino acids, e.g., caffeine and theobromine.

**Bioactivity of Alkaloids:** Alkaloids possess great chemical flexibility which brings about enormous biological activity. A single alkaloid can change its structure and play multiple functions depending upon the cellular conditions. This ability makes them a unique set of secondary metabolite compounds. Studies on the alkaloids produced by the *Amaryllidaceae* family shows that they function as analgesics, antivirals, anti-malarials, antineoplastics properties and also exhibit some effects on the central nervous system (Tadeusz 2007). Another, alkaloid fagaronine obtained from the *Fagara zanthoxyloides* Lam. (Rutaceae) has been known for the hemoglobi-nization of human leukemic cells (Dupont et al. 2005). Quinoline alkaloids obtained from the genus *Haplophyllum* A. Juss. (family Rutaceae) are associated with estrogenic effect (Nazrullaev et al. 2001). According to Caron et al. (1988), 34 quasi-dimeric indole alkaloids showed potent antibacterial activity against gram positive bacteria like *Staphylococcus aureus* and *Bacillus subtilis*. Other organisms which were found susceptible to 31 different alkaloids are *B. subtilis*, *S. aureus*, *Mycobacterium smegmatitis*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Candida albicans*, and *Aspergillus niger*. An alkaloid allosecurinine was tested for the normal process spore germination of some saprophytic and pathogenic fungi, e.g., *Alternaria alternata*, *A. solani*, *A. brassicicola*, *A. brassicae*, *Curvularia lunata*, *C. pallescens*, *C. maculans*, *Curvularia species*, *Fusarium udum*, *Colletotrichum species*, *C. musae*, *C. gloeosporioides*, *Erysiphe pisi*, *Helminthosporium echinoclova*, *H. penniseti*, *H. spiciferum*, and *Heterosporium* sp. It has been noticed that it resisted mild spore germination of all the fungi tested whereas depicted high efficacy against *Curvularia lunata*, *Curvularia* sp., *Collectotrichum* sp., *C. musae* and *Heterosporium* sp. by complete inhibition of spore germination at very low concentrations (Singh et al. 2007). They also had extensive use in agriculture in the past where they were used as salts of nicotine and anabasine as insecticides (Matolcsy et al. 1988).

Thebaine, an alkaloid obtained from opium has been used to develop a new drug naloxone, which

is an opioid receptor antagonist (Dewick 2002). Many alkaloids like ajmaline, caffeine, atropine, colchicine, codamine, etc. are still used in medicines the form of their salts.

## Conclusion

Many alkaloids have been used for several hundreds of years in medicine and even today they are prominent sources of drugs. In most of the human history, alkaloids from plant extracts have been used as ingredients in liquid medicine and poisons. Ancient people used plant extracts containing alkaloids for treating a large number of ailments including: snakebite, fever, and insanity. Therefore, more research is required not only to completely understand the therapeutic potential of alkaloids but also to increase their production through tissue culture techniques.

[Allele sharing methods; Identity by descent \(IBD\)](#)

## Definition

The sharing of alleles of certain genes and/or markers among siblings and related individuals.

## Introduction

The concept of allele sharing is derived from the Mendelian law of segregation of alleles. Two siblings (sibs) can exhibit allele sharing which is identity by descent (IBD) due to inheritance from a common parent. Sharing of allele can also be incidental when the reason for sharing is not known and is known as identity by state (IBS). According to Mendelian segregation rules, the probability that pair of siblings would share both marker alleles = 0.25, one marker allele = 0.5, and zero marker allele = 0.25. This follows the Mendelian expected ratio of 1:2:1.

## Allele Sharing Methods

These are popular nonparametric analytical methods used for the study of complex disorders. Affected sib-pair (ASP) analysis is one of the common and simplest of allele sharing methods (Fig. 1). If affected siblings or relatives share the

**Allele Sharing, Fig. 1** Affected sibpair analysis. Two affected sibs (S1, S2) and their parents (P1, P2) are represented. One affected son, S1 receives alleles 1/6 from her parents. Assuming Mendelian random segregation, his brother, S2, can either receive the same set of allele, IBD = 2 (as shown) with a probability of 0.25 or only one of them i.e., 1/6 or 3/6, IBD = 1, with a probability of 0.5 or receives a different set i.e. 3/4, IBD = 0, with a probability of 0.25 (zero sharing). If the marker is linked to the disease locus, the probability of the sharing of marker alleles will be increased in affected sibpairs (Drawn as interpreted from Lander and Schork (1994))

same alleles more often than chance, it may imply an association between allele and the disease. This might occur due to linkage between the marker alleles and the disease gene or candidate gene (Risch 1990; Lander and Schork 1994).

The classical parametric methods for linkage analysis rely on transmission disequilibrium test and are based on LOD scores. These methods therefore require the knowledge of inheritance mode of the loci, allele frequencies, number of loci affecting the disease phenotype, penetrance estimations, etc. Such methods are very successful in mapping genes or markers for Mendelian genetic disorders. However, in the case of complex disorders like diabetes, asthma, schizophrenia, and Alzheimer's, these methods might not prove helpful. Inheritance of complex disorders doesn't follow Mendelian genetics, and there are multiple loci influencing these disorders. Genotype-environment interaction also plays a big role in the manifestation of these disorders. It is often difficult to estimate mode of inheritance, allele frequencies, and penetrance expression in such cases.

Allele sharing method is a model-free non-parametric method and does not make any assumptions on mode of inheritance. It simply analyses whether the inheritance pattern of markers is consistent with Mendelian segregation. Sharing methods compare the actual sharing with the random probabilities, and a significant deviation indicates linkage. However, these methods usually involve studies on very large samples of sib pairs. Usually, such methods are used along with linkage analysis (Risch 1990; Whittemore and Halpern 1994; Kruglyak et al. 1996; Kong and Cox 1997). Allele sharing data is observed to increase the power and efficiency of disease – marker association studies – and helps in search for variants that predispose to complex disorders (Fingerlin et al. 2004). Allele sharing methods can be used for the analysis of qualitative as well as quantitative traits, whereas affected sib-pair method is used to investigate the possible sharing of maternal or paternal alleles by IBD. The analysis of quantitative traits by this method involves the understanding that siblings that share more alleles at a locus by IBD

should be phenotypically more similar than siblings that share fewer alleles. In a study carried out on 80 sib pairs affected with juvenile rheumatoid arthritis (JRA), excess sharing of two HLA-DR alleles was observed among ASPs with JRA (Prahalad et al. 2000). Similar studies for other complex genetic disorders like osteoarthritis (Callegaro et al. 2010) and venous thromboembolism (DeVisser et al. 2013) demonstrate the use of allele sharing methods for increased efficiency of linkage analysis.

## Conclusion

Allele sharing methods are important analytical tools for complex genetic disorders as they are nonparametric in nature and are therefore advantageous over parametric methods. However, studies need to be carried out on large samples of sib pairs or related individuals for effective interpretations, although determining the mode of inheritance of major susceptibility genes in a complex disorder may provide useful information to understand the disease.

[Allelomorph](#)

## Definition

Alleles are variant forms of a gene that differ in sequence information.

## What Are Alleles at Genetic Level?

The term allele refers to variant forms of a gene. A gene can be considered as any stretch of the DNA that gets transcribed, i.e., gets converted to RNA. So, a gene is basically a sequence of nucleotides that is characterized by its specific loci or position in the genome.

The nucleotide sequence information of a gene can have variants and each variant of the gene having a different sequence is referred to as an allelic form or allele of the gene.

A gene may have a single or multiple allelic forms.

## How Do Allelic Forms Arise?

Allelic variants arise due to mutations, i.e., changes in the sequence information (Watson 2014). Suppose a gene has a single allelic form having a particular sequence. In course of time, the sequence can get changed due to variety of factors, and the new form with the changed sequence is considered as a new allelic form of the same gene.

## How Do Alleles Function Differently?

It is the sequence information of the gene that determines the product that it is going to form. Alleles differ in sequence information and site of the variation determines the type of change observed:

- A change in the coding sequence may result in alteration in the amino acid sequence of the resultant protein. Such changes may or may not affect the structure and functionality of the protein.
- A change in splice sites may induce larger-scale changes with splice variants being formed.
- Changes in regulatory regions have the potential to alter the transcription rate and therefore the abundance of the product.

Changes in untranslated regions can alter the RNA stability and therefore the abundance of the product.

It is also possible that an allelic variant may not affect the protein functionality or abundance. But whenever there is a significant change in functionality or abundance of a gene product, it alters the overall cellular processes under its control and gives rise to an alternate phenotype.

## Example of Allelic Systems: Single, Two, Multiple

While a few genes may have single allelic forms, most of the genes are polymorphic, i.e., they have multiple allelic variants at the population level. Technically, a gene is defined as polymorphic if the rarer allele has an abundance of at least 1% at the population level (Futuyma 2006).

Historically, the most abundant allelic form of a gene in a population was referred to as the wild type allelic form, while the other rarer forms were considered as mutant types. Now it is known that most alleles are highly polymorphic and the population frequency of different allelic forms depends on the particular population under consideration. What is wild type in a particular population can be a rare form in another population.

It must be remembered that the maximum number of alleles an individual organism can have is equal to its ploidy, i.e., the number of haploid sets it possesses. For diploid organisms like humans, maximum two allelic variants are possible in a single organism. Likewise, haploid organisms have single allelic forms, while tetraploids may have as many as four allelic variants in one individual. If an organism possesses the same allelic form of a gene in each of its homologous chromosomes, then it is considered as homozygous for that gene. If the allelic forms are different, then it is considered as heterozygous for that locus.

Therefore, the maximum number of allelic variants that an organism can possess is limited by

the number of haploid sets. Polymorphism exists at the level of population and not individual.

For example, human AB blood group has three major allelic forms, A, B, and O at population level, but an individual may only have maximum of two allelic forms.

Major histocompatibility complex genes, which form a crucial element of our immune system, have hundreds of allelic variants.

**Dominant and Recessive Alleles**

Alleles can be either dominant or recessive in terms of their expression (Snustad and Simmons 2003). If an allelic form can express its phenotype in heterozygous configuration, i.e., when other allelic forms are also present in the organism, then its expression is said to dominate over the expression of the other alleles, and such alleles are considered as dominant alleles. The allele whose expression is suppressed by the dominant counterpart is considered as the recessive allele. Such recessive alleles require homozygous condition to express their phenotype.

It must be understood that dominance and recessiveness are relative phenomenon. Consider three allelic forms for fruit color: A1 (red), A2 (pink), and A3 (white). Allele A2 may be recessive to allele A1 such that a genotype A1A2 would show phenotype of A1 (red). But the same recessive allele A2 may be dominant to allele A3 in a way that A2A3 shows phenotype of A2 (pink). In the first case, A1A2, allele A2 is recessive, while in the second case, A2A3, the same allele A2 is dominant. So the dominance hierarchy is as follows for these three alleles

$A1 > A2 > A3$ . It is evident that the dominance or recessiveness of an allelic form depends on the other allelic form it is paired with and thus it is a relative phenomenon. Dominance is the relationship between two alleles of a gene and their associated phenotypes (Table 1).

Dominance and recessiveness are only applicable in heterozygous context.

Sometimes, the resultant phenotype may be a mixed expression of the two participating alleles. For example, flower color allele B1 (red) and allele B2 (yellow) in heterozygous condition B1B2 would produce a mixed orange color phenotype. In such a configuration, allele B1 and B2 are considered to be incompletely dominant over each other.

Alleles can also be codominant where both allelic forms express at the same time. ABO blood group is a prime example where individuals with AB genotype show simultaneous expression of A as well as B form of the glycoprotein on their red blood cell surface.

**Determination of Allelic and Genotype Frequencies in a Population**

For populations following the assumptions of Hardy–Weinberg equilibrium, the allelic and corresponding genotype frequencies can be calculated from each other by simple mathematical relations.

Hardy–Weinberg equilibrium assumes the following (Hartl and Clark 2007):

- 1. Organisms are diploid.
- 2. Sexual reproduction is the sole mode of reproduction.

**Alleles, Table 1** Table showing dominance hierarchy between multiple allelic forms of a gene

| Genotype | Allele 1 | Allele 2 | Phenotype of allele 1 | Phenotype of allele 2 | Phenotype of organism | Dominance status of allele 1 | Dominance status of allele 2 |
|----------|----------|----------|-----------------------|-----------------------|-----------------------|------------------------------|------------------------------|
| A1A1     | A1       | A1       | Red                   | Red                   | Red                   | Homozygous                   | Homozygous                   |
| A2A2     | A2       | A2       | Pink                  | Pink                  | Pink                  | Homozygous                   | Homozygous                   |
| A3A3     | A3       | A3       | White                 | White                 | White                 | Homozygous                   | Homozygous                   |
| A1A2     | A1       | A2       | Red                   | Pink                  | Red                   | Dominant                     | Recessive                    |
| A2A3     | A2       | A3       | Pink                  | White                 | Pink                  | Dominant                     | Recessive                    |
| A1A3     | A1       | A3       | Red                   | White                 | Red                   | Dominant                     | Recessive                    |

- 3. Mating is random.
- 4. Population is infinitely large.
- 5. Generations are nonoverlapping.
- 6. Allele frequencies are same in both sexes.
- 7. No selection pressure is operative.
- 8. Mutation is not taking place.
- 9. No genetic drift or migration of organisms.

For a two allele system, the relation is as follows:

$$p + q = 1 \text{ and } p^2 + 2pq + q^2 = 1$$

where,

- p = frequency of allele p
- q = frequency of allele q
- p<sup>2</sup> = frequency of genotype pp
- q<sup>2</sup> = frequency of genotype qq
- 2pq = frequency of genotype pq

**Allelic Variants Contributing to Genetic Disorders**

As allelic variants alter the function of the gene product, it is understandable that a number of variants can contribute to genetic disorders.

Many genetic disorders are caused by recessive alleles, where the heterozygotes act as “carriers” of the trait. The phenotype of the disorder is only evident in the homozygous individuals possessing two copies of the mutant allele. Lethal genetic disorders are mostly recessive in nature because otherwise the dominant lethal allele would prevent the deleterious allele from being passed on to next generation. Dominant lethal alleles can arise by spontaneous mutations but they are rarely propagated. Sometimes dominant lethal alleles may propagate if the onset of the disease is after the attainment of reproductive age (Table 2).

**Implications at Population Level**

At the population level, selection pressure determines the prevalence of any allelic form of a gene (Hartl 2012). If the prevailing conditions would

**Alleles, Table 2** Genetic disorders seen in humans and nature of the causative alleles. X-linked, Y linked, and autosomal mean that the corresponding gene loci are on X-chromosome, Y-chromosome, and autosomal chromosome, respectively

|                     |                                                                   |
|---------------------|-------------------------------------------------------------------|
| Autosomal dominant  | 1. Huntington’s disease<br>2. Familial hypercholesterolemia       |
| Autosomal recessive | 1. Sickle cell anemia<br>2. Cystic fibrosis<br>3. Phenylketonuria |
| X-linked dominant   | 1. X-linked hypophosphatemia<br>2. Rett syndrome                  |
| X-linked recessive  | 1. Duchenne muscular dystrophy<br>2. Red-green color blindness    |
| Y-linked            | 1. Azoospermia<br>2. Swyer syndrome                               |

favor a certain allelic variant, the frequency of that allele would keep increasing as long as the selection pressure is operative.

Consider this hypothetical example. Gene C controls body color of an insect X. Allele C1 produces green body color while allele C2 produces red. The insects live in lush green vegetation. Crows prey on these insects. Which allelic form would benefit the insects? Obviously allele C1 as it would allow better camouflage on the backdrop of the lush green vegetation. Therefore, as long as the crows are preying on the insects (selection pressure), the frequency of allele C1 would keep increasing. Insects having allele C2 will be preyed upon and eliminated.

Another very well-known real-life example is of the sickle cell anemia. Sickle cell anemia is caused by a mutant allelic form of hemoglobin. This mutant form is prone to polymerization and distorts the normal shape of RBCs, making them prone to breakage. In homozygous state, this mutation leads to deleterious condition sickle cell anemia. Normally this trait provides no advantage on the normal human physiology and heterozygous individuals show minor physiological problems.

Interestingly, in areas where Plasmodium malaria is prevalent, this mutant allelic form is much more and occurs at a much higher

frequency. Plasmodium needs RBCs to complete their life cycle. Mutant hemoglobin allele makes the RBCs prone to degradation and unsuitable for Plasmodium life cycle. Hence this mutant form is selected in heterozygous condition to make individuals resistant to Plasmodium malaria. This phenomenon is known as heterozygote superiority. This is a very elegant example of how varying selection pressure can alter the abundance of different allelic forms among populations.

In a situation where natural selection does not favor any particular allelic form, the abundance of different alleles would remain constant through generations.

In summary, alleles are the underlying factor which has made possible the amazing diversity we see in this world. Crossing over, random distribution of chromosomes, and other factors contributing to diversity are all dependent on the presence of allelic variants in the first place.

## Definition

Allelic association refers to the statistical association between an allele and the observed phenotype. It measures the frequency of co-occurrence of the allele and observed phenotype in a population, which is more than expected and nonrandom (i.e., not by chance). It is a population-specific characteristic, hence varies among populations and doesn't require observation of parental transmission of gametes carrying alleles.

## Introduction

Allelic association is an important parameter in population genetics to investigate genetic etiology of complex traits or diseases (Lowe and Reddy 2015). An allele is each of the two or more alternative forms of a gene present at a single locus on a chromosome. Allelic association refers to the statistical association of an allele to an observed phenotype, or a trait, in a population which is more than expected and nonrandom (i.e., not by chance). In simpler terms, it is an observation that how much

**Allelic Association, Fig. 1** Allelic association of a complex disease. (In affected group frequency of allele “R” is significantly more than allele “r” indicating its association with the observed complex disease in the studied population)

the variations in genotype correlate to the phenotypic variations. Let us take an example; assume that Fig. 1 indicates occurrence of a complex disease in a population. In genetic analysis, it is found that frequency of allele “R” is significantly higher than allele “r” in affected than nonaffected group; which gives a deduction that it has an allelic association with the observed complex disease.

A closely related but distinct concept is “linkage disequilibrium (LD)” or “gametic disequilibrium.” LD denotes random associations of alleles across loci located on the same chromosome, i.e., LD is an inter-allelic association rather than between an allele and a phenotype. LD arises due to faults of crossing over during meiosis in a gametic phase and its effect diminishes with time in the process of evolution due to recombination events in innumerable meiotic divisions which would shift loci and break inter-allelic linkage. The term “linkage disequilibrium” and “allelic association” should not be used interchangeably. Salient differences between allelic association and LD have been provided in Table 1.

Types

Allelic association to a trait may be direct – showing a cause-effect relationship, or indirect – through intermediary markers. A third type of association may be spurious, where apparent association is not linked to the genetic etiology.

**Allelic Association, Table 1** Allelic association versus linkage disequilibrium (LD)

| Allelic association                                                             | Linkage disequilibrium (LD)                                           |
|---------------------------------------------------------------------------------|-----------------------------------------------------------------------|
| Unrelated subjects can be studied; knowing the family pedigree is not essential | Subjects should be in genetic relation; family pedigree must be known |

Allelic Association Mapping Using Single Nucleotide Polymorphs (SNPs)

An allelic association can be studied searching single nucleotide polymorphs (SNPs) in candidate regions (Collins et al. 2001), or in genome-wide association studies (GWAS) (Bush and Moore 2012). A SNP arises from a single base-pair change at any locus in the DNA sequence, which occurs with high frequency in animal genome. SNPs are the chief source of genetic variations and play an important role in etiology of several complex and multifactorial diseases. Susceptibility or protection to a particular disease has been found well correlated with several polymorphisms. Association mapping studies identify functional polymorphisms (polymorphism producing an effect in gene function) that predispose to complex diseases. Population-based approaches are concerned with exploiting allelic associations between the SNPs and disease-predisposing loci (Collins et al. 2001). The 1000 Genomes Project Consortium provides an extensive online database of SNPs across worldwide populations, a highly valuable source for studying genetic etiology of common diseases (The 1000 Genomes Project Consortium 2015). Computational technology has revolutionized the statistical analysis of allelic association. ALLASS is publicly available software for mapping a disease locus by allelic association (Collins and Morton 1998).

## Allelic Association Versus Linkage

Allelic association denotes that frequency of a single or group of alleles at a gene locus is correlating with the observed phenotypic outcome. In comparison, linkage gives an indication that a particular region of a chromosome which is showing enhanced linkage signaling for the used probe markers for a phenotypic outcome contains the causative alleles. Hence, allelic association analysis is a high-resolution study which would point to a gene locus or a particular allele (which would be a few base pair long), and linkage is a low-resolution study which only indicates to a specific segment of a chromosome (a segment is limited by breaking sites of a chromosome during meiosis event for recombination and each may contain few thousands of base pairs). In this sense, a prior linkage analysis for a phenotypic outcome narrows down the search in the whole genome (which contains about 3 billion base pairs) to a particular chromosomal segment (containing a few thousands of base pairs) where a causative allele should be searched for.

## Allelic Association Analysis

There are two designs commonly used for studying allelic association, one is population based (or proper case-control study) and another is family based. In a population-based study, a difference of the allelic frequency at particular loci is measured between the case – in which observed phenotype is present and a control – in which observed phenotype is absent. As the allelic frequency may naturally vary between different populations and in the sections of a single population, so a population-based study may be confounded by naturally occurring allelic variations in subsections of a population, a concept which is called “population stratification” (Wang et al. 2006). The family-based designs take care of the natural variation of allelic frequency in segments of the population, in which comparison is made between participants from the same family. Allelic frequency variation is measured in parents who

bear the allele and phenotype is expressed in the offspring (case) and compared with the other parents belonging to the same family who bears the allele but the phenotypic effect is not transferred to the offspring (control).

The science of investigating causal genes or alleles or a DNA segment for a phenotypic variance is called “reverse genetics” (Griffiths et al. 2000). The identification of a particular gene or allele responsible for the observed phenotypic variance can be done by “positional cloning” (a common method used in reverse genetics) which involves three steps: (i) “meiotic mapping” which allows identifying DNA segments containing causal gene or allele (Lodish et al. 2000), (ii) physical mapping which includes sequencing of the marked DNA segment (O’Rourke 2014), and (iii) finding mutation in the decoded sequence and verifying its functional role. The intermediary marker alleles (which are showing increased frequency with the observed phenotype but not create a cause-effect relationship) can be also used to locate a causative allele or gene which can be further reached by sequencing of the DNA segments in proximity. Any significant difference in allelic frequency between the genetically unrelated case and control (population-based study) can be tested by the classical Pearson’s  $\chi^2$  test. If case and control are genetically related (family-based study), transmission disequilibrium test (TDT) can be applied which is based on allele transmission rate between genetically related individuals (Ewens and Spielman 2004).

## Introduction

Allogrooming is a form of caregiving through physical contact, typically where one animal uses its hands, mouth, or other part of its body to touch another animal (Dunbar 2010; Newton-Fisher and Kaburu 2017; Spruijt et al. 1992). The mechanical motion of grooming resembles scratching, picking, stroking, or rubbing (in some animals licking and nibbling) and is directed towards the outer body surface, whether that surface is fur, feathers, or bare skin (Dunbar 2010; Pellis and Pellis 2010; Spruijt et al. 1992). Grooming is widely studied in primates (Dunbar 2010; Newton-Fisher and Kaburu 2017; Schino and Aureli 2010; Spruijt et al. 1992), but it occurs in a wide variety of other animals too, including arthropods, birds, and other mammals such as ungulates and rodents (Pellis and Pellis 2010; Spruijt et al. 1992). The word “allogrooming” means “grooming another” and usually refers to same-species grooming. The functions of allogrooming (why it exists and what the benefits are) are many and varied (Spruijt et al. 1992), but there are two main functions: (1) allogrooming provides a cleaning service, and (2) it confers a social benefit.

## Hygiene

Cleaning is the primary function of allogrooming across all animals who do it (Spruijt et al. 1992). For example, in many insect species, allogrooming plays a very important role in disease control. Insects have been observed to remove pathogens from each other's bodies through allogrooming (Zhukovskaya et al. 2013). Among birds, the definition of grooming overlaps with the definition of "preening," and hence the term "allopreening" is used (Spruijt et al. 1992). Allopreening has been shown to have an important cleaning function in birds. For example, in a study of pigeons, the incidence of allopreening in test pairs was found to have an inverse relationship to the number of lice found in the feathers of those pairs (Villa et al. 2016). The cleaning function is also well known in mammals, particularly primates (Spruijt et al. 1992). For example, in a study of allogrooming in baboons, those individuals who received more grooming had fewer ticks in their fur and were consequently healthier than those who received less grooming (Akinyi et al. 2013).

## Sociality

Beyond the cleaning function, allogrooming is integral in the social repertoire of many species (Dunbar 2010; Pellis and Pellis 2010; Spruijt et al. 1992). Allogrooming is a markedly intimate social pastime, requiring the focused concentration of the groomer and the sitting-still willingness of the groomee. Gupta and Sinha (2016), studying wild bonnet macaques, observed how attentively the groomer responded to gestures of the groomee. For example, if the groomee held out its tail while being groomed elsewhere on its body, the groomer switched its grooming attention to the tail. The same would happen if the groomee moved other parts of its body into the attentional gaze of the groomer: the groomer would switch to grooming the area that the groomee gestured towards. In fact, the investigators determined that groomers responded "appropriately" (switching grooming to the body part

indicated) to more than 94% of pertinent gestures, a result which illustrates the keen two-way sensitivity that constitutes allogrooming behavior. In the everyday lives of animals, allogrooming is often mixed in with other social bonding behaviors such as social play (Pellis and Pellis 2010). Social touching is a vital constituent of many animal societies (Dunbar 2010; Pellis and Pellis 2010; Spruijt et al. 1992). When two individuals engage in a grooming bout, it creates pleasure for the groomee because the tactile stimulation causes the release of endorphins in the groomee's body (see review in Dunbar 2010), which helps strengthen the social bond between the two animals (the groomee associates that groomer with pleasure) and it also reduces tension (Dunbar 2010; Russell and Phelps 2013).

## Grooming Markets

Allogrooming is therefore a valuable behavior: it cleans, it reduces tension, it is a social bonding mechanism, and it feels pleasurable to receive. Because of this value, scientists have studied allogrooming as a kind of natural version of money. For example, 10 min of grooming is a "parcel," a finite period during which the groomer is providing a service to the groomee. Hence, one can think of this parcel of grooming as a kind of payment, with a benefit to the receiver and (presumably) some cost for the giver (Russell and Phelps 2013). Using this idea of grooming as a currency, an animal society can be viewed as a "marketplace" wherein commodities (such as allogrooming) can be traded back and forth somewhat like money (see Dunbar 2010; Newton-Fisher and Kaburu 2017; Schino and Aureli 2010; Russell and Phelps 2013). In most primate species, grooming happens often (Dunbar 2010) and therefore scientists have devoted considerable attention to the issue of grooming *reciprocity*: where an "animal... makes a direct trade of 10 min of grooming for 10 min of being groomed" (Dunbar 2010, p. 263) (10 min is therefore a "parcel size"). In a meta-analysis of 14 primate species across 25 different datasets, Schino and Aureli (2010) tested whether reciprocity is an

important explanatory factor in a primate's decision to start grooming someone (i.e., groom those who have given you grooming in the past) – in contrast to the influence of kin selection (i.e., groom those who are members of your family group). They found that reciprocity played a larger role than kin selection in explaining allogrooming efforts, a result that demonstrated the importance of allogrooming as a tradeable currency in primate societies.

### Allogrooming as Chimpanzee Politics

Allogrooming is a decision. At a given time, an animal chooses to start grooming someone else. In a complex social setting, there might be various factors that influence that decision. As described above, a primate may choose to groom as a form of reciprocation (Schino and Aureli 2010). However, a social group often consists of more than two individuals. Imagine a group of three individuals. There, the decision becomes one of preference: you can only groom one at a time, so your decision about whom to groom depends on your preference. The decision becomes further complicated if the group has four, five, six, or more. This becomes the marketplace as described above: you have a commodity to give or to receive, and a number of individuals with whom you can choose to groom. Far beyond a simple cleaning task, a chance to bond socially or to pay back a favor – the grooming decision in a large group becomes political. One can look at the chimpanzee study of Newton-Fisher and Kaburu (2017) to illustrate the complexities of a grooming decision. Specifically, they investigated the influence of two other variables: *dominance* and *bystander effects* (both described below). Observing a large group of chimpanzees ( $N = 63$ ) at the Budongo Forest Reserve (Uganda), the investigators focused on the allogrooming of eight adult males. These males differed from each other in their dominance rank, which was calculated based on the outcome of aggressive interactions between the males: for each observed fight, a winner and a loser was determined – a male was recorded as being a loser if he was observed “screaming, cowering or

running away, or receiving but not returning physical violence and/or wounds” (Newton-Fisher and Kaburu 2017, p. 156). The dominance hierarchy was established by counting the wins and losses, and ranking the males accordingly (the alpha was the male with the most wins compared to losses). They then calculated “rank distance” by subtracting lower scores from higher scores. This means that, for each pair of males, they had a score of how far apart the males were on the dominance hierarchy (e.g., the first and fifth most dominant had greater rank distance than the first and second). The other important variable in the study – the bystander effect – referred to the effect of having other chimpanzees in the vicinity of an allogrooming event, but not participating in the focal grooming.

Based on their data, Newton-Fisher and Kaburu (2017) had a number of results that showed how grooming decisions in chimpanzee males were influenced by the interaction of rank distance and bystander effect. They had six main significant results. The first result concerned the beginning of a grooming bout, when a subordinate male approached a dominant male and started grooming. They measured “initial investment,” which referred to how long the subordinate male spent grooming the dominant before the dominant responded in any way (e.g., starting to groom back). In other words, the investment is the degree of grooming effort that a subordinate is willing to expend with no payoff. They compared a number of different grooming pairs, with varying extents of rank distance between pairs. They found that with greater rank distance, the initial investment was greater. This illustrates how subordinates were willing to invest substantial unreciprocated grooming effort depending on their position in the hierarchy. Clearly, allogrooming is a kind of strategy that subordinate males were using in response to dominance – and the degree of effort invested depended on rank distance. Other results obtained in this study involved bystanders and how dominant the bystanders were. They found that, if bystanders were high-ranking, the initial investment and the parcel size were lower than if the bystanders were not as high-ranking. This showed that the mere presence of a dominant male had an

effect on a chimpanzee's grooming decision, even though that dominant was not directly involved. A related analysis was the rank distance between the bystander and the groomee. They found that initial investment was lower commensurate with the rank distance. In other words, the groomer tended to invest less grooming to the groomee if the bystander outranked the groomee. Finally, the study had two results related to the reciprocation of grooming – specifically, whether the groomee would pay the grooming back while being groomed. They found that reciprocation was more likely if there were fewer bystanders. They also found that grooming was more likely to be reciprocated if there was a smaller rank distance between the two groomers. Overall, the results of Newton-Fisher and Kaburu (2017) illustrate how allogrooming is more than an isolated event between two individuals. Allogrooming is, for many animals, an essential protocol in their social politics.

## Allometry

Kjetil Lysne Vøje

Centre for Ecological and Evolutionary Synthesis (CEES), Department of Biosciences, University of Oslo, Oslo, Norway

Allometry, in a broad sense, describes how phenotypic traits change with changes in overall body size. Biological variation in a large range of physiological, morphological, ecological, and life-history traits is highly correlated with variation

in organism size, and the concept of allometry represents important hypotheses for understanding this trait variation.

## The Allometric Model

Allometric scaling relationships are described by power functions, often referred to as allometric equations. They have the form  $Y = aX^b$ , where  $b$  is the scaling exponent that describes how the trait  $Y$  relates to changes in the overall size variable  $X$ . When  $b = 1$ , traits enlarge proportionally to overall size, a case which is referred to as isometry. The shape of the organism will not change with changes in overall size if traits scale isometrically. When  $b \neq 1$ , the size of the trait will change in different proportions to changes in overall size, and the shape of the organism will change with changes in overall size. Allometric relationships with an exponent smaller than 1 are referred to as negative allometry, while relationships where  $b > 1$  are referred to as positive allometry.

A power function yields a linear equation on a log-log scale,  $\log(Y) = a + b\log(X)$ , where  $b$  is the allometric scaling exponent. The conventional way of estimating the parameters in an allometric scaling relationship is to fit a least square regression on log-transformed trait and body size data. The log-transformation of the data is not to linearize the relationship but to analyze the data on a proportional scale, assuming errors are multiplicative rather than additive (Kerkhoff and Enquist 2009). The  $a$  parameter represents the intercept of the linear model and will equal the mean of the trait if the body size data are centered around zero before fitting the linear model.

Variation in body size exists at several levels and three different types of allometries have traditionally been recognized based on three different sources of variation in body size (Cheverud 1982). Two types of allometry are estimated using within-species data: Ontogenetic allometry refers to the scaling relationship between a trait and body size during the growth of individuals, while static allometry refers to the observed scaling relationship between a trait and body size

across individuals measured at a similar developmental stage. Evolutionary allometry refers to the scaling relationship observed among population or species means.

## Examples of Allometric Relationships

Allometric scaling relationships have been important for structuring knowledge of size variation of traits (Schmidt-Nielsen 1984). An example is the scaling relationship between brain mass and body mass, which has attracted interest for more than a century. Although empirical estimates of the allometric exponent ( $b$ ) in the relationship between brain and body mass among mammal species vary, it is always found to be less than 1. The negative allometric scaling relationship of brain size across species indicates that brain mass does not generally increase in equal proportion to increases in overall body size. In other words, given their smaller body size, shrews have a proportionally larger brain size than elephants. The allometric model also allows an assessment of which species having a smaller or bigger brain size than predicted by their body size. For example, according to a study by Boddy et al. (2012) who studied the allometric scaling relationship between brain mass and body mass in more than 600 species of mammals, baleen whales have brain sizes less than predicted by the allometric model given their body mass, while humans have a brain size much larger than the predicted value.

Allometric scaling relationships have also inspired hypotheses explaining how and why specific traits scale the way they do. For example, the positive allometry hypothesis claims secondary sexual traits almost universally exhibit positive static allometry ( $b > 1$ ) since a steep allometric exponent will evolve if an increased relative trait size yields increased fitness (see Bonduriansky 2007 for a review of the positive allometry hypothesis). Another popular hypothesis is the negative allometry ( $b < 1$ ) of genitalia in spiders and insects, often explained by the advantage of males having genital sizes that are appropriately adjusted to the most common size of internal genital structures in females (Eberhard 2009).

Although these hypotheses often hold, traits under natural selection show both positive and negative allometry, which suggests that steepness of the allometric exponent is not a reliable indicator of the type of selection that has operated on a trait (Voje 2016).

### Allometry Reflecting Adaptation or Constraint?

To what extent ontogenetic allometries are expected to predict static and evolutionary allometric relationships is debated. Hypotheses explaining evolutionary allometries fall in two broad categories: those based on developmental constraints and those based on functional adaptation between traits and overall size. Huxley (1932) showed that if two morphological traits grew in proportion to each other, variation in growth rate would necessarily produce a scaling pattern between them that follows a power relationship. If the growth relationship of a particular trait is more or less fixed among species, evolutionary changes are bound to follow trajectories imposed by ontogenetic or static allometries, meaning evolutionary allometries must be similar to these. Partially supporting the allometry as constraint hypothesis is the observation that ontogenetic and static allometries are found to be rather invariant and tend to predict evolutionary divergence below the species level, but less so on longer time scales (Voje et al. 2014). An alternative explanation of the low variability of static and ontogenetic slopes is that natural selection favors particular scaling relationships between traits and overall size. Attempts of changing the static slope in artificial selection experiments have indeed succeeded, but the changes have been very small, indicating a low evolvability of the allometric slope parameter (Bolstad et al. 2015).

### Definition

“Alloparental care” is care that is directed by an individual (an alloparent) toward dependent young that are not their offspring (Wilson 1975). The act of providing alloparental care is referred to as “alloparenting.”

### Types of Alloparental Care

Alloparental care has been reported widely across the animal kingdom, specifically in birds (Koenig and Dickinson 2004), fishes (Wisenden 1999), invertebrates (Wilson 1971), and mammals (Solomon and French 1997). Animals employ a variety of strategies to produce and rear their young, which influences the ways that alloparents can contribute care. Most birds, fishes, and invertebrates lay eggs, while all mammals (aside from monotremes) give birth to live young. In most mammals, milk is the sole medium of nutrient intake for young during the first stage of life. In other taxa, young immediately feed on similar materials to mature individuals, either with the assistance of foraging parents (or alloparents), as in birds, or independently, as in fishes. These differences in the ways that animals rear their young have led to the diversity of alloparental care expressed across the animal kingdom;

alloparental care encompasses a wide array of behaviors, including allonursing, food provisioning, grooming, nest building, territory defense, thermoregulation, and transport.

### Alloparental Care Across Breeding Systems

Alloparental care is exhibited by animals living across a range of social systems. These behaviours occurs mostly in group-living animals classified among three types of breeding systems: eusocial, cooperative, and communal. “Eusocial breeding” is when a dominant breeding pair is assisted by permanently nonbreeding alloparents to rear their offspring. Alloparents specialize in specific types of care, which can result in behavioral, morphological, and physiological differences between alloparents with different specializations, often referred to as castes. Eusocial breeding has been reported in invertebrates, such as ants, bees, termites, and wasps, as well as two mammalian species, the Damaraland mole rat (*Fukomys damarensis*) and the naked mole rat (*Heterocephalus glaber*). “Cooperative breeding” is when a dominant breeding pair is assisted by nonbreeding alloparents to rear their offspring, with more flexible parameters than eusocial breeding; alloparents need not specialize in one type of offspring care over their entire lives. In cooperative breeders, alloparents are often the dominant breeders’ offspring that have not yet dispersed from their natal territory. Cooperative breeding is relatively common among birds, while less so in mammals and fishes. “Communal breeding” is when offspring care is shared by multiple breeding individuals that can also be assisted by temporarily nonbreeding alloparents. Communal breeders do not necessarily need to breed at the same time, meaning that individuals can take turns breeding and providing care for one another’s offspring. Most social animals that are not eusocial or cooperative breeders can be considered communal breeders due to the more relaxed definition (i.e., cetaceans, bats, elephants, most primates, lions; Solomon and French 1997, pp. 1–10). While communal breeding is common

in mammals, it is relatively rare among birds and fishes.

In species that breed eusocially, cooperatively, or communally, alloparents and breeders live together and thus often have ongoing social interactions. Alloparental care is also exhibited by “solitary breeders,” which are common across the animal kingdom and include birds, fishes, insects, and mammals. Solitary breeding is when young are raised by one or two individuals, which can be either the genetic parent(s) and/or an alloparent. Alloparental care in these types of breeders can occur following the eviction, voluntary leave, or death of a genetic parent(s) and subsequent replacement by an individual that provides care for the young that were left behind (termed “adoption” in some species). Adoption can also occur when parents actively transfer (or farm out) their offspring to an alloparent that provides care for their young (Wisenden 1999).

### Misdirected Parental Care

Alloparental care can be misdirected parental care, when individuals are deceived into providing care for another individual’s offspring as a result of ineffective or absent kin recognition mechanisms. In these cases, an alloparent is unable to differentiate between young that they themselves produced and another individual’s young. In birds and fishes, this can occur when individuals lay their eggs in the nest of another breeder (termed “brood parasitism”). Some fish species may also covertly deposit their gametes at competing individuals’ spawning sites. In mammals, females have been observed to mate with multiple males to confuse paternity in an attempt to secure care from multiple males (termed “cuckoldry”). This may result in a male providing care for dependent young that are not his own offspring but that he believes to be his own based on past mating behavior. For the remainder of this entry, we will focus on alloparental care that is not a result of misdirected parental care. Below, we discuss the ultimate and proximate drivers of alloparental care, with selected examples from three vertebrate taxa: birds, fishes, and mammals.

## Evolution of Alloparental Care

### Fitness Benefits of Alloparental Care to Parents and Their Offspring

There is evidence in many species that alloparental care improves parents’ long-term survival, their future reproductive success, and/or the fitness of their current offspring (Tanaka et al. 2018; Russell et al. 2007; Brouwer et al. 2012). The distribution of fitness benefits among parents and their offspring depends on the ways that parents respond to alloparental care. Their responses can vary widely, with parents maintaining their care (termed “additive effects”) at one end of the spectrum and reducing their care to offset alloparental care (termed “load-lightening effects”) at the other end (Hatchwell 1999). For instance, in birds that exhibit additive effects, hatchlings will be provisioned with more food as the number of alloparents visiting the nest increases. Conversely, in birds that exhibit load-lightening effects, parents will reduce their provisioning rates as the number of alloparents increases and hatchlings will receive the same amount of food regardless of alloparental number. The way that parents respond to alloparental care varies across the animal kingdom, with some species showing additive effects, some showing load-lightening effects, and some showing an intermediate response (Hatchwell 1999). Load-lightening effects have also been documented in response to *expected* alloparental care through a reduction in prenatal parental investment. For instance, in some bird and fish species, mothers that anticipate assistance from alloparents based on group composition will reduce their offspring investment at the egg-laying stage, leading to smaller eggs and thus, smaller hatchlings (Dixit et al. 2017). Smaller hatchlings that are provided with additional care from alloparents exhibit “catch-up” growth and, ultimately, attain the same sizes that they would have if their mothers had laid larger eggs. The way that parents respond to alloparental care ultimately represents a trade-off between current and future offspring investment. Load-lightening effects tend to increase parents’ survival and future reproductive success, while additive effects tend to increase the fitness

of their current offspring. Across the animal kingdom, alloparental care influences the fitness of parents and/or their offspring in various ways, as shown in the next paragraph.

Alloparental care can shorten the amount of time that elapses between births and increase the size of the litter or brood in species where multiple offspring are produced at a time. For instance, alloparental care in mammals can increase mothers' energy balance because they are able to forage more often or more efficiently, or rest more while their offspring are cared for by alloparents. This can increase mothers' milk nutrient densities and improve the nutrient intake of offspring during nursing bouts. This leads to accelerated offspring growth and earlier weaning, which can allow mothers to return to estrous more quickly and, ultimately, increase their lifetime reproductive output (Solomon and French 1997, pp. 11–33; Mitani and Watts 1997). There is limited evidence that alloparental care impacts the long-term survival of parents; however, this has been shown in some species (i.e., superb fairywrens, *Malurus cyaneus*; Russell et al. 2008).

In many species, there is evidence that alloparental care improves the lifetime survival and/or reproductive success of offspring. This has been attributed to the fact that offspring that receive alloparental care tend to be heavier at independence. Heavier offspring are more likely to survive in the long-term, reproduce for the first time at a younger age, and/or be more attractive to the opposite sex (Hodge et al. 2009; Russell et al. 2007). Lastly, in some social species, affiliative interactions during infancy (the time from birth to the end of weaning) that occur between alloparents and young can be maintained throughout life. These social bonds can lead to life-long fitness benefits for both parties (Maestripieri 1994).

### Fitness Costs of Alloparental Care to Alloparents

There is compelling evidence across the animal kingdom that alloparental care can be costly to the alloparent (Heinsohn and Legge 1999). Alloparents will incur different costs depending on the type and frequency of support that they provide to young as well as their own developmental

stage. To provide care, alloparents often forego foraging time, which can lead to weight loss (or failure to gain weight). Alloparents across taxa may spend time babysitting other individuals' young to ensure that they are warm and safe from predators. This can have substantial costs for the alloparent. For instance, individuals that spend the day babysitting can lose body weight throughout the day, while those that forage with the group will gain weight (Clutton-Brock et al. 1998). In addition to lost feeding time, alloparental care can be costly if behaviors are energetically demanding. Two of the most energetically demanding forms of alloparental care are allonursing and transport (Solomon and French 1997, pp. 11–33). “Allonursing,” when females nurse young that are not their own offspring, is highly energetically demanding and has been reported in a wide variety of mammals, including primates, cetaceans, and canids (MacLeod and Lukas 2014). Transport is a behavior mostly reported in primate species, as young are transported with the rest of the group throughout the day immediately following birth until they can locomote independently (Fig. 1). In addition to incurring high-energy expenditure, transport likely reduces alloparents' feeding efficiency as well as their agility when moving through trees, which can have consequences when fleeing from predators (Solomon and French 1997, pp. 11–33). There are also many mouth-brooding fishes where

**Alloparental Care, Fig. 1** Female ursine colobus monkey (*Colobus vellerosus*) holding the infant of the female to her right. (Photo by Stephanie Fox)

alloparents transport other individual's young in their mouth, which impedes their ability to feed (Wisenden 1999). Provisioning young with food items can also be costly, although the costs of provisioning will depend on a species' foraging strategies. In contrast to birds and mammals, most fish species do not provision their young with food. This narrows the potential costs of alloparenting to elements of predator protection and burrow maintenance.

Weight loss (or failure to gain weight) can have substantial fitness impacts on alloparents in the long term, particularly in alloparents that are still developing into adults. As mentioned above, individuals that are heavier at independence often have higher reproductive success; thus, if alloparental care reduces individuals' ability to gain weight, it could have long-term fitness consequences (Lindström 1999). In species where alloparental care is provided by mature and/or postreproductive individuals, weight loss is likely less costly in the long term. There is compelling evidence across taxa that alloparents incur costs when providing care. Why then should animals engage in these behaviors, if they are not just cases of misdirected parental care? Despite the fitness costs associated with providing care to another individual's offspring, there are inclusive and direct fitness benefits that alloparents can accrue.

### **Inclusive Fitness Benefits of Alloparental Care to Alloparents**

Alloparents can increase their inclusive fitness (their own direct fitness and the direct fitness of their genetic relatives) if care is directed toward related individuals that benefit from the additional care ("kin selection" hypothesis, Hamilton 1964). Across the animal kingdom, there is limited evidence that alloparents adjust the amount of care provided to reflect their genetic relatedness to care recipients (Clutton-Brock 2002). In many cases, this can be explained by the membership and social dynamics of animal groups. For instance, there is clear evidence in many species that, when alloparents select care recipients, they discriminate between kin and non-kin. For example, alloparental care in primates and cetaceans may be

biased toward maternal female kin, especially among populations in which females live and reproduce in their natal group and matrilineal social bonds are maintained throughout life (Fedigan 1982). Older, postreproductive females can play key roles as alloparents in these species. For females of species with long life-histories, several of which experience menopause, it may be more beneficial for older individuals to help rear the offspring of their adult progeny, rather than to continue investing in their own reproduction ("grandmother hypothesis"; Hawkes and Coxworth 2013). Thus, in many species, alloparents do in fact discriminate when choosing their care recipients, and this is based on preferred social relationships that may reflect a shared kinship. Furthermore, in species where social groups comprise closely related individuals, mechanisms that allow alloparents to discriminate among care recipients based on genetic relatedness may be redundant. Nonetheless, there are still species where alloparental care is directed toward unrelated individuals or even where relatedness reduces the amount of care provided by alloparents; direct fitness benefits may better explain the evolution of alloparental care in these species.

### **Direct Fitness Benefits of Alloparental Care to Alloparents**

There are many ways that alloparents can accrue fitness benefits directly, regardless of their relatedness to care recipients. While inclusive fitness benefits are more generally applicable across taxa, direct fitness benefits will vary according to the species-specific ways that animals survive and reproduce. Below, we discuss the most commonly cited direct fitness benefits of providing alloparental care. First, alloparental care can afford immature individuals the opportunity to practice their parenting skills, which increases the likelihood that they will successfully rear their own offspring in the future ("skill" hypothesis; Selander 1964, p. 206). This is especially important in species in which offspring care involves a novel skill that, prior to parenthood, is not part of daily life. In birds, reproductive success tends to be lower in younger, less experienced breeders. This has been attributed to a lower reproductive

effort but also to less experience in providing care for dependent young. Immature individuals that are able to practice building a nest and caring for eggs and hatchlings will likely be more successful at rearing their own offspring. In primates, transport is an important element of offspring care, and a major source of infant mortality for arboreal primates is being dropped from trees. Thus, immatures who hold and carry other individuals' offspring may have more success as adults in carrying their first offspring. The "skills" hypothesis has been supported in a variety of other bird and mammal species, leading some researchers to declare this as a major driver of alloparental care in their study taxa. Second, alloparents could accrue direct fitness benefits if their contribution increases their social status among other group members ("social prestige" hypothesis; Zahavi 1995). For instance, alloparental care in many species can be a way for males to signal to potential mates that they are high-quality parents, increasing their mating opportunities. In many species, males that provide care for other individual's offspring are afforded more mating opportunities in the future, either with the offspring's mother or other females. Providing care can allow for alloparents to build or strengthen beneficial social relationships with parents and their offspring. These social bonds can have fitness benefits for alloparents in the long-term. For instance, in species showing dominance hierarchies, low-ranking individuals may benefit through coalitionary support, grooming, and tolerance while feeding, from high-ranking individuals following the contribution of alloparental care to the dominant individuals' offspring (Maestripietri 1994). Lastly, the "group augmentation" hypothesis posits that, if alloparents are better able to survive and/or reproduce in larger groups, they can benefit directly from contributing to the rearing of new group members, regardless of their relatedness (Kokko et al. 2001). There are many benefits associated with living in larger groups, including reduced predation risk through dilution and more alloparents to assist with rearing future offspring. In fish, alloparents can facilitate the survival of their own young by arranging other individual's young at the edge of

the brood to deflect predators from their own offspring. Furthermore, by adopting other individual's young that are smaller in size and more likely to be targeted by predators, they can improve the likelihood that their own offspring will survive (Wisenden 1999). In conclusion, we emphasize that these direct benefits are species-specific and thus, while we have provided evidence in some taxa, there is also evidence that these benefits do not occur in others. Furthermore, inclusive and direct fitness benefits of alloparental care are not mutually exclusive and thus, they could be collectively driving these behaviors.

## Proximate Drivers of Alloparental Care

### Role of the Parents

Parents in many species take an active role in alloparental care. As mentioned previously, alloparental care can be a result of misdirected parental care. In these cases, parents use behavioral tactics (i.e., cuckoldry in mammals, brood parasitism in fishes and birds) to ensure that their offspring are cared for by alloparents. Furthermore, some parents are able to use their dominant status to solicit alloparental care. For instance, subordinate individuals that provide more care are less likely to be evicted from their natal group by dominant breeders, securing access to communal resources and nepotistic benefits ("pay-to-stay" hypothesis; Gaston 1978). Alloparental care appears to compensate for the costs that subordinates impose on dominants by residing in their territory and/or social group (i.e., competition for limited resources). In some species, dominant breeders will even coerce subordinates into providing alloparental care, with evidence for this in some species (i.e., naked mole rats, *Heterocephalus glaber*; superb fairywrens, *Malurus cyaneus*; Lake Tanganyika cichlids, *Neolamprologus pulcher*) but not in others (i.e., meerkats, *Suricata suricatta*) (Santema and Clutton-Brock 2012).

On the other hand, parents in some species will actually reject alloparental care when there is potential for the offspring to be harmed. Parents may be less permissive of alloparents that are

inexperienced if the care entail risks. For instance, in primates, the inexperience of younger alloparents may lead to clumsy interactions and cause harm to the infants (i.e., falls from trees) (Maestriperi 1994). Additionally, in groups with strong dominance hierarchies, low-ranking primates may have difficulty retrieving their offspring from higher-ranking alloparents and thus be more resistant to relinquish their offspring to other individuals. A failure to retrieve one's own offspring can have detrimental consequences for the offspring, particularly if it is unable to obtain milk from the mother, a phenomenon referred as "aunting-to-death" (Maestriperi 1994). Thus, in some species, the extent to which alloparental care is exhibited may depend more on maternal permissiveness than on the motivation of alloparents.

### Alloparent Age, Sex, and Physical Condition

In the castes of eusocial insects, alloparents specialize in different types of care and individuals can develop behavioral, morphological, and physiological differences (Wilson 1971). This type of permanent specialization in alloparental care has not been confirmed in any species of bird, fishes, or mammal. Regardless, the tendency for alloparents to contribute care can still vary based on a variety of factors, including age, sex, and physical condition. This has been attributed to state-dependent costs and benefits of providing alloparental care (Cockburn 1998).

When there are sex differences in the amount of alloparental care contributed, it is the philopatric sex that tends to provide more care (Clutton-Brock et al. 2002). Individuals from the philopatric sex remain and breed in the group in which they were born. Thus, the philopatric sex is more likely to accrue direct fitness benefits from alloparental care (i.e., group augmentation, social bonds) than the dispersing sex, which explains why the philopatric sex tends to provide more alloparental care. Alloparents can also modify the amount of care that they provide based on the offspring's sex, often favoring the philopatric sex as these are the individuals that will remain in the social group in the long-term. The amount of alloparental care provided can also be influenced

by the age of the alloparents (Zöttl et al. 2016). When immature individuals provide alloparental care, the amount of care provided tends to decrease as alloparents prepare to disperse and/or invest in their own reproduction. As age and weight are often correlated, it can be difficult to disentangle the ways that these two factors impact alloparental care. There is, however, some evidence that, when accounting for age, heavier individuals are generally more likely to contribute alloparental care (Clutton-Brock et al. 2002).

## Etymology

From Greek *allo* meaning “other,” and *patric* meaning “home.”

## Synonyms

Geographic speciation

## Definition

Speciation caused by geographical isolation.

Speciation is the evolutionary process from which new species originate. There are three main recognized modes of speciation: allopatric, peripatric, and sympatric. Here, we will focus on allopatric speciation.

Allopatric speciation occurs when there is geographic isolation and consequently, no ► [gene flow](#) between separated populations, allowing these newly isolated populations to evolve separately. This is usually caused by some geographical barrier splitting the population into two (or more) subpopulations. These geographic barriers can vary and include mountains, rivers, islands, and others (see examples below). A few individuals may cross this barrier in some cases, but the gene flow remains reduced, maintaining the speciation process. Other events that affect populations of a species, such as local diseases, can also isolate populations, generating similar consequences as those of geographical barriers (Ridley 2009). Allopatric speciation would be considered a type of ecological speciation since ecological differences (as environment and niche) are directly involved in the speciation process, acting as barriers.

Because of the isolation, however caused, subpopulations no longer exchange genes, and their reproductive isolation (see definition below) begins to gradually increase as a result of ► [mutation](#), ► [genetic drift](#), and effects of ► [natural selection](#). In general, the environmental differences to which these subpopulations are exposed impose specific selective pressures, which, in turn, may select more adaptive individuals (Mayr 2001). Eventually, each subpopulation's genome begins to restructure and diverge from the rest of their ancestral population. The length of time that this geographic isolation persists culminate in the species' genetic differentiation (Dobzhansky 1951).

It is possible to discriminate two types of events that can cause geographical isolation: dichopatric (allopatric vicariance) and peripatric speciation. The primary difference between both types is the population size. Dichopatric

speciation events, which usually isolate large populations, are caused by the rise of a geographical barrier, such as the drying up of a stretch of a river splitting a previously contiguous population (as shown in Fig. 1), or the elevation of sea level, isolating part of a previously contiguous population on an island. In peripatric speciation, a small part of the ancestral population becomes geographically isolated by establishing a new territory on their distribution periphery. This isolation may occur either by the appearance of a new geographic barrier or by dispersion through an existing one. By colonizing new areas beyond the species distribution range, this population experiences founder effects and may pass through a genetic bottleneck (Fig. 2). Since usually only a few individuals colonize new regions, they carry only a small ► [gene pool](#) of their original population. As a result, these individuals may be potentially exposed to high selection pressure imposed by the new environment. This combination makes this population more prone to extinction, and at the same time facilitates their genotype restructuring, allowing it to differentiate from their ancestral population (for more details see Mayr 2001).

## Reproductive Isolation

Reproductive isolation occurs when members of two or more different populations cannot reproduce with each other or generate only nonviable descendants. In this case, a population is prevented from interbreeding with other populations due to geographical barriers or other mechanisms (e.g., physiological, morphological, and temporal barriers). This isolation can be caused by two different categories of barriers: pre-zygotic, which acts before mating or fertilization, such as a geographical barrier; and post-zygotic, which acts after fertilization, such as zygote abnormality. Post-zygotic mechanisms usually arise from accumulated mutations in each of the isolated populations, which, when united in a hybrid, cause loss of fitness. This phenomenon is called Dobzhansky-Muller incompatibility.

**Fig. 1** Allopatric speciation caused by the rise of a geographical barrier (dichopatric)

A

**Brief Historical Perspective**

Understanding the diversity of species and elucidating the mechanisms that generate them have always been of interest to evolutionary theorists and, in fact, are the main questions that motivated Darwin's studies. In 1835, the geologist Leopold Von Buch pointed out the importance of geographical barriers as demarcating different "genus" (following the Aristotelian genus sense). However, allopatric speciation was not documented until the 1940–1960s, by Ernst Mayr. Geographic isolation culminating in reproductive isolation was important to Mayr and his biological concept of species, reinforcing the genetic basis of speciation presented by Theodosius Dobzhansky in 1937. The concept of allopatric speciation was crucial for the understanding of the speciation phenomenon, and this geographical approach generated a subsequent

productive field of evolutionary studies, functioning as the basis of most species concepts currently recognized, as well as the unified concept of species (for details, see de-Queiroz 2007).

**A Classical and Current Example****Darwin's Finches**

Darwin's finches are one of the most classic examples of allopatric speciation and ► [adaptive radiation](#). Approximately 15 species of finches evolved from a single ancestor group that colonized Galapagos' archipelago islands in South America. Because geographic isolation prevented gene flow, each population evolved independently under the natural selection pressures imposed by each island. This evolution is evident when looking at birds' different beak shapes that vary according to each island's available food and

**Allopatric Speciation,****Fig. 2** Allopatric speciation caused by founder effects (peripatric)

consequently with the bird's feeding habit. For instance, some of the finches have beaks adapted to eat cactus flowers without getting scratched, while others are adapted to breaking hard nuts. These adaptations are clear examples of how natural selection and speciation can act over time, differentiating one species into two or more species, each adapted to their new environments.

**Sydney Octopus**

Until 2014, there were two recognized populations of the Sydney octopus *Octopus tetricus* in Australia: one from the far east, and another from the far west, which some authors considered as possibly being two different species. It is known that these two populations were isolated within the last 3.2–6.9 million years. This period coincides with the cooling of the previously tropical Miocene seas along the southern Australian coastline and the Bassian Isthmus's rising during the Pliocene era. For many

Australian species, the glacial-interglacial epochs during the early Pleistocene resulted in a northward progression of cooler waters, causing some species to retreat along the eastern and western coasts isolating populations, which allowed genetic differentiation among them (Amor et al. 2014). Recently, a study combining molecular and morphological data proposed a new taxonomy of *Octopus tetricus*, delineating *Octopus tetricus* into two species, which probably diverged by allopatric speciation (Amor et al. 2014).

Despite being an old concept, allopatric speciation is still part of a fruitful field in science. With the advent of molecular dating techniques, it is now possible to precisely identify which geographical barriers acted as insulators between taxonomic groups. This recent, but important, step has created new avenues to be explored by researchers from different fields, allowing a deeper understanding about the patterns and processes that are part of each lineages' history speciation.

## Definition

In animals living with a hierarchical organization, alpha is the highest ranking individual, also called dominant.

## Introduction

Social animals frequently organize themselves in dominance hierarchies. In this hierarchical organization, individuals have different access to resources. The highest animal in the rank is the alpha and their position is maintained through agonistic interactions, so the alpha is the individual who wins fights over all others (Cafazzo et al. 2010). Male, female, or both (normally a reproductive couple) can be alphas, depending on the social organization of the specie.

Normally, alpha animal is the individual in the group that monopolizes most of the resources as food, mates, spatial location, and territory (see examples below). Alpha position can be attained through aggression and intimidation or collaborating and with the support of subordinates (Sapolsky 2005).

## Who Will Become the Alpha?

Social and physical characteristics will influence who will become the alpha individual, and this will vary a lot among species. However, older individuals normally dominate younger ones (Cafazzo et al. 2010; Creel 2001). Size is also a good predictor of dominance, with bigger individuals dominating smaller ones (Whiteman and Côté 2004).

## Why Is Good to Be the Alpha?

Dominance interactions denote competitive interactions about resources over which most group-living animal species compete, such as food, mates, spatial location, and territory. The extent to which resources are divided unequally among individuals varies as a function of the dominance style of different species (Sapolsky 2005). However, in most species the alpha has a higher portioning of resources.

In most cooperatively breeding birds and mammals, reproductive rates are higher for dominants and its common that the alpha is the only one that reproduces (Creel 2001).

Dominant orangutan males, for example, have more pronounced secondary sexual characteristics and, besides that, can suppress the development of subordinate individuals, making them appear “juvenile” (Sapolsky 2005).

Food partitioning is also observed in dogs, with alpha gaining access to food prevailing over the other in the group (Cafazzo et al. 2010). The alpha also has the privilege to steal food from other group members who often did not react (Cafazzo et al. 2010). Dominant may also have higher foraging rates, as for example in cleaning gobies (fish), because the alpha monopolizes areas with higher food density (Whiteman and Côté 2004). In experimental and controlled conditions, dominant fish eat more than subordinates in the dwarf cichlid *Apistogramma agassizii* (Kochhann et al. 2015).

Spatial centrality in the group for dominants has been described for many species (such as primates, spiders, fish, and birds) (Hemelrijk 2000).

## The Alpha Position and Stress

Although the dominant position has some privileges, it is not free of charge. Some characteristics of the social hierarchy can make the alpha position the most stressful of the rank. Dominants have elevated glucocorticoid, a response related to elevated stress when a hierarchy is unstable or in species in which dominants fight more often than do subordinates (Creel 2001).

Higher stress markers are also observed in alpha individuals where they have to repeatedly and physically reassert their rank; those that are cooperative breeders; and those with transient periods of major rank instability (Sapolsky 2005).

## Conclusion

Alpha is the highest rank individual in a dominance hierarchy. The alpha position is achieved through agonistic interactions and determines the individual that will have a privilege in accessing resources.

|------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Single strategy                    | One strategy with two or more alternative tactics. The environment determines which tactic an individual chooses and also whether ARTs have different or same mean fitness. The single strategy combines the mixed and the conditional strategy, emphasizing the importance of the environment in determining fitness outcomes. |
| Bourgeois tactic                   | The tactic with the highest possible fitness.                                                                                                                                                                                                                                                                                   |
| Best of a bad job                  | An individual follows a tactic with a lower fitness than an alternative tactic, because it is not competitive enough to successfully follow the bourgeois tactic.                                                                                                                                                               |
| Relative plasticity hypothesis RPH | The RPH is based on the assumption that differences between ARTs are similarly regulated via hormones as are the differences between the sexes.                                                                                                                                                                                 |

Introduction

Alternative reproductive tactics (ARTs) refer to the consistent use of different reproductive behaviors between conspecifics of the same sex in one population at the same time. Hereby the difference between individuals is discontinuous, such that one can put individuals into two or more categories. A tactic refers to the behavioral phenotype, which results from a strategy. A strategy can have different tactics, e.g., territorial male versus satellite male. If a strategy has only one tactic, then more than one strategy must be present in the population for ARTs to be present. It is typically tactics which are studied, not strategies.

Examples of ARTs in Males and in Females

ARTs are more common in males than in females, probably because reproductive success in males is more skewed than in females. For example, in

species in which a few competitive males monopolies the access to fertile females, smaller and less competitive males might develop best of a bad job tactics to mate with these females and gain at least some reproductive success before being big enough to be a dominant male. If more than one reproductive tactic occurs in a population, then ARTs occur. This is basically the case in every species where apart from bourgeois males (see below), another type of males occurs that are trying to fertilize females. In males, the following tactics have been described:

- **Bourgeois male:** These are males which follow the tactic with the highest mean fitness. Thus, these are the most competitive and most dominant males, which often defend a territory and/or a group of breeding females (harem).
- **Sneakers:** These are small males trying to sneak copulations with females defended by bourgeois males. Satellite males, roamers, and floaters are different types of sneaker males. Sometimes this term is used for roamers and floaters in reptiles, which means for subordinate males that are not (like satellite males) associated to a specific territory. Sneaker males occur in many lizard species such as marine iguana (*Amblyrhynchus cristatus*) and tree lizard (*Urosaurus ornatus*), and in cichlid fish such as *Lamprologus callipterus*.
- **Satellite males:** These males are associated to a specific territory but do not defend a territory themselves. They are typically less competitive and smaller than bourgeois males. They try to mate with females in the territory they are associated with. In some species like bluegills (*Lepomis macrochirus*), these males have female mimicry, meaning they look and behave like females, explaining why the bourgeois males do not chase them away. Satellite males occur in many lizard species such as marine iguana (*Amblyrhynchus cristatus*) and tree lizard (*Urosaurus ornatus*), in tree frogs and several species of crickets.
- **Roamers:** This term is usually only used for mammals. Roamers typically have a well-defined home range that is very large and

overlaps the home range of several bourgeois males but not defended as a territory. These males roam over a large area, trying to avoid the bourgeois males but to meet and to copulate with any females they encounter. Example: African striped mouse (*Rhabdomys pumilio*).

- **Floaters:** This term is used mainly for birds and mammals. Floaters are males that, in contrast to roamers, do not have a well-defined home range, but float through the population, trying to copulate with females defended by bourgeois males. Floaters occur in many bird species such as the red-winged blackbird (*Agelaius phoeniceus*).
- **Helpers:** Helpers are males that help a breeding pair to raise the pair's offspring i.e., they help to raise young that are not their own. In many species, helpers also try to fertilize eggs/females, either of the pair they are helping (cichlid *Neolamprologus pulcher*; pied kingfisher *Ceryle rudis*), or of neighboring groups (African striped mice, meerkats *Suricatta suricata*; superb fairy-wrens, *Malurus cyaneus*).

While ARTs have been mostly studied in males, female ARTs also occur. This is the case when the investment of other females such as maternal care can be exploited or when females monopolies the parental investment of males by forming one female-multiple male groups, mating polyandrously. As ARTs are alternative ways to gain fitness via reproduction, alternative mating tactics, such as monogamous versus polynadrous mating of females also represent ARTs, but such alternative mating tactics are difficult to measure and received little attention. In females, the following ARTs have been described:

- **Solitary versus communal breeding** in African striped mice, house mice, and probably many other small mammals.
- **In eusocial insects**, workers that are laying eggs in the nest dominated by a queen.
- **In some wasps**, females can either join the nest of another female (communal breeding) or start their own nest (single breeder).
- **Female dunnocks** can mate monogamously, polyandrously, or polygynandrously.

- Fire ants (*Solenopsis invicta*) females can form colonies with either one single monogynous queen or colonies with several breeding females.

### Species With and Without Morphological Differences Between ARTs

In some species, males following different tactics do not only differ in their behavior but also in their morphology. For example, in several lizard species with ARTs, the different tactics also differ in the coloration of their skin, such as the coloration of dewlaps in tree lizards. In species with genetically determined alternative strategies, males can differ dramatically in size, for example, in the cichlid fish *Lamprologus callipterus*, where bourgeois males are 10 cm long and weight 36 g, while dwarf males reach only 2.5 cm and 0.9 g. In some case, such as dwarf males parasitizing bourgeois males, the reason for the phenotypic difference is obvious. In contrast, why male lizards following ARTs differ in coloration is still not understood, and this question also received little scientific attention. Many studies on ARTs focused on such species where the different tactics can easily be distinguished, as obviously this makes it easier to study ARTs. However, in the huge majority of studies, individuals following ARTs differ mainly in behavior and often additionally to a small, not always (to the observer) obvious extent in body mass. Thus, species where ARTs are also phenotypically different are a special case.

### What Does Not Represent ARTs?

No examples of ARTs are interspecific brood-parasitism, sex change, simultaneous hermaphroditism, and infanticide (Taborsky 2008). In many species, each male might have different tactics to fertilize females, without these representing ARTs. For example, in most passerine birds, males are pair-living, copulating with their female partner, and additionally seeking to

copulate with neighboring females to gain extra-pair paternity. As all males follow this strategy, it does not represent ARTs, as there is no consistent variation between males. However, if it would be shown in one species that some males invest heavily in guarding their mate and not in extra-pair copulations, while other males don't invest in mate guarding but in extra-pair copulations, then this consistent variation would represent ARTs.

Alternative tactics can also occur in other behaviors than reproduction. For example, alternative dispersal tactics have been described in African striped mice (*Rhabdomys pumilio*), where the largest males disperse over short distances (less than 500 meters), intermediate males over large distances (several kms), and small males not at all (Solmsen et al. 2011). While these alternative dispersal tactics are correlated with ARTs (territorial male versus roaming male versus philopatric males), they do not represent ARTs themselves but rather a tactic of males of intermediate body mass to reach the high fitness tactic of territorial male in a distant subpopulation instead of becoming a roamer in the natal population. Similar alternative tactics that are not reproductive tactics can occur for different foraging strategies.

The occurrence of an alternative male (or female) morph that does not reproduce is not regarded as ARTs. Thus, traditionally cooperatively breeding species with nonbreeding helpers have not been considered as examples of ARTs. However, more detailed studies often found that helpers might breed when the opportunity arises, without changing their social status. Examples for this are female workers of many hymenopterans, male helpers in meerkats, in striped mice and in superb fairy-wrens, and helpers of both sexes in the cichlid *Neolamprologus pulcher*.

### Strategies Underlying ARTs

It is important to differentiate between the observed tactic and the underlying strategy (Gross 1996). A strategy refers to decision rules which determine which alternative tactic is

shown. A strategy has a strong genetic basic but is not totally genetically fixed, as there is variation between individuals, for example, when exactly to switch from one tactic to another. The strategy is determined by specific mechanisms which are a response to environmental cues. An example for a strategy might be the following decision rule: If you are larger than X, increase your testosterone level and become a territorial male, otherwise be a satellite male.

It has been stated that the differentiation between strategies and tactics is not useful as both relate to the same issue (Taborsky 2008). However, the differentiation between strategy and tactic can be very important, as it clearly indicates one shortcoming in our understanding of ARTs: Nearly all research has focused on the tactics themselves, i.e., the fitness consequences and the underlying endocrine mechanisms leading to ARTs (all the rest of the current article reviews this), while the underlying strategies have been ignored. Thus, for most species showing ARTs the underlying decision rules have never been estimated, tested, and validated. However, formulating these decisions rules can help us with coming up with better and more meaningful predictions, for example, about the expected fitness consequences of ARTs. On the other hand, if no clear set of decision rules (a strategy) can be formulated, this indicates a lack in our understanding of the ARTs of this specific species.

For male African striped mice, it has been proposed that they have one strategy, the decision rules of which determines which of the three possible ARTs a male follows, while the environment determines the fitness outcomes (Schradin and Lindholm 2011):

1. Decision: To remain philopatric to your natal group or to disperse?
  - (a) Remain a philopatric male if all females breed in communal groups defended by breeding males and your body mass is below the population mean and there are more sexually mature males than female groups in the population. Mate with any female from neighboring groups.
  - (b) Leave your natal group if:

- (i) At any time of the year, a breeding position becomes vacant in a neighboring group which you can fill.
  - (ii) At the beginning of the breeding season if population density is low and several single undefended females are present in the population which has a female biased sex ratio.
  - (iii) At the beginning of the breeding season if your body mass is above the mean of the population, independent of population density.
2. Decision: To become a roamer or try to become a territorial breeder?
  - (a) If all female breed solitarily then become a roaming male.
  - (b) If you find a group of communally breeding females that are not defended by a male that is larger than you then become the breeding male of this group, defend the territory of this group against other males, and try to copulate with all your females plus all females from neighboring groups.

This set of decision rules makes clear that being a roamer can be the result of two different processes: (1) an active choice, because many females breed solitarily and roaming is the best tactic or as good as being a territorial breeder. (2) Result of low competitive ability, i.e., the male chose to disperse and would choose to become a territorial breeder, but he cannot, because all communal female groups are defended by larger males. This is similar to the situation in stoplight parrotfish (*Sparisoma viridae*) where males start with the tactic of bachelor and the availability of free territories and their relative body size determines when they can switch to the territorial tactic (Cardwell and Liley 1991).

## Development and ARTs

The tactic an individual follows to have reproductive success develops during its life and can change during development (Fig. 1). Obviously, the time point when an individual reaches sexual

**Alternative Reproductive Tactics, Fig. 1** A simplified overview of the different pathways that can lead to ARTs, adapted from (Taborsky 2008). Top: ARTs can arise out of two (or more) different main genotypes determining which of the alternative tactics is expressed in each individual. Middle: One genotype can lead to ARTs via nonreversible developmental plasticity, where one out of two (or more) alternative pathways leading to ARTs is chosen. Empirical evidence for his mechanism leading to ARTs is missing. In contrast, most cases of ARTs are due to flexibility, i.e., reversible phenotypic plasticity, for example, many cases

where males follow either a best of a bad job or a bourgeois tactic, depending on their relative competitiveness. In some tree frogs, the biggest males are calling, smaller males are satellites, but when bigger males arrive/disappear, males can immediately switch their tactic, and later can switch again. Bottom: One main genotype can lead to ARTs when individuals follow different tactics during their development, for example, following a doing the best of a bad tactic as young small adults, and changing to the bourgeois tactic when older and more competitive

maturity is important for the expression of its reproductive tactic. In species where the reproductive tactic is genetically fixed, the tactic that an individual will follow throughout its life will then be expressed. If depending on the genotype two or more alternative tactics might be expressed, then we observe ARTs in this population (Fig. 1, top). In other species, it's the environment that determine which of two (or more) ARTs is expressed (Fig. 1, middle). However, especially in males, whether or not individuals can reproduce not only depends on when it reaches sexual maturity but also on its competitiveness, for which body mass is often a very good proxy. Large dominant males might reproduce, while small males, even though sexually mature, might have to wait and grow, possibly forming bachelor groups of nonbreeding males or remaining as nonbreeding subordinate males in a group.

There is strong selection pressure on individuals to reproduce, and accordingly in many species subordinate males are trying to mate with females, even when being small and dominated by larger males that try to monopolies access to receptive females. Such small males might follow a best of a bad job tactic, often called satellite or sneaker tactic, until they become larger and can follow the dominant bourgeois tactic (Fig. 1, bottom). In these species, which tactic is followed is mainly determined by growth after reaching adulthood, and as such determined by development during adulthood. While some authors do not regard such development dependent tactics as ARTs, they clearly are, as we need (1) ultimate explanations for the occurrence of such best of a bad job tactics which are (2) controlled by specific endocrine mechanisms, which evolved to maximize lifetime reproductive success.

Tactics can be genetically fixed or plastic (Fig. 1). Within the plastic tactics, developmental

plasticity might lead permanently to one out of several alternative tactics, which the individual then cannot change anymore. The sequence of tactics might also be developmentally fixed, for example, from small sneaker to large bourgeois male, as described above. However, in many species, individuals can flexibly change their reproductive tactic repeatedly. This is also a form of plasticity, which in contrast to fixed developmental plasticity is called flexibility.

### Evolution of Strategies Underlying ARTs

The phenomenon of alternative reproductive tactics has been analyzed by game theory, where a tactic refers to a specific behavior resulting from individual decision rules, so-called strategies. Reproductive tactics have a strong influence on individual fitness and are thus under strong selection pressure. However, it is rather the underlying

strategies, i.e., developmental and cognitive decision rules that evolve and then produce the observed tactics. In a classical paper, Gross (1996) defined three categories of strategies (Fig. 2):

1. Alternative strategies: Genetically polymorphic, based on frequency-dependent selection. Different tactics yield the same average fitness. Examples are giant versus dwarf males of the cichlid fish *Lamprologus callipterus*. Alternative strategies are represented by genetically fixed tactics in Fig. 1.
2. Mixed strategies: Genetically monomorphic, based on frequency-dependent selection. Different tactics yield the same average fitness. No good empirical examples exist. Mixed strategies have also been characterized by a probabilistic basis, i.e., a probability  $x$  to play tactic  $X$  and probability  $1-x$  to play tactic  $Y$ . These represent developmental fixed plastic tactics in

**Alternative Reproductive Tactics, Fig. 2** Bottom: Traditional categorization of reproductive strategies (decision rules leading to tactics) by Gross (1996) and top modified by Schradin and Lindholm (2011). Differences between strategies refer to whether the shown tactic is genetically fixed (Alternative Strategies) or not (all other strategies).

While Gross (1996) further differentiated whether the fitness of ARTs is similar (Mixed Strategies) or different (Conditional Strategies), Schradin and Lindholm (2011), see the fitness outcome as variable depending on the current environmental conditions (Single Strategy)

Fig. 1, where tactics have the same average fitness and the chosen tactic then depends on the frequency of all tactics in the population.

3. Conditional strategies: Genetically monomorphic, based on status-dependent selection. Different tactics yield different fitness. The tactic that an individual chooses depends on its competitive abilities. The most competitive individuals follow the tactic that yields the highest fitness payoff, called the bourgeois tactic. Less competitive males (often called sneaker or satellite), that are smaller and younger than the bourgeois males, make the best of a bad job, following a tactic with lower fitness that is still better than no reproductive success at all. These males change to the bourgeois tactic when they grow larger. Many examples exist in both vertebrates and invertebrates. These represent flexible (reversible plasticity) and developmental sequenced tactics in Fig. 1.

Empirical studies on the African striped mouse revealed that fitness consequences of ARTs can be environment dependent. Male striped mice follow one of three ARTs: (1) Territorial breeding males defend a group of communally breeding females; (2) Solitary roaming males trying to copulate with any females they encounter; (3) Philopatric males that remain in their natal group and try to sneak copulations with females from neighboring groups. Under high population density, breeding males have 10 times higher reproductive success than roamers and 100 times higher reproductive success than philopatrics. However, under intermediate population density, breeding males and roamers have the same mean fitness, and no philopatrics occur (as all sexually mature males leave their natal group). Under very low population density, all males follow a roaming tactic, and some of these roamers have a very high reproductive success, higher than that of breeders under high population densities. These observations lead to the formulation of the single strategy, which contains both the mixed and the conditional strategy proposed by Gross (1996; Fig. 2).

The single strategy is a new term introduced by Schradin and Lindholm (2011) to replace the terms

mixed and conditional strategy, which differ mainly in the predicted fitness consequences (equal fitness for mixed versus different fitness payoffs for tactics arising from conditional strategies). Single strategies are not based on genetic polymorphisms, but all individuals follow the same or very similar decision rules when choosing a tactic. Individuals have flexible tactics, which means they can switch tactics, often repeatedly. Environmental conditions determine whether the different tactics yield similar or different fitness. By formulating the single strategy (=decision rules; see above) for striped mice, it became evident that fitness outcomes depend on the prevailing environment. To become a roamer can be the result of a male choosing to disperse and to roam, as the tactic yields high fitness. Alternatively, it can be the result of a male choosing to disperse and attempts to become a territorial breeder but not being competitive enough to do so. In the latter case, being a roamer would be a best of a bad job tactic.

The definitions by Gross (1996) have been criticized on theoretical grounds because of its focus on genetic polymorphism versus genetic monomorphism: even if different animals follow very similar decisions rules and show flexibility, i.e., they can change between tactics, they still might differ genetically, e.g., in their decision when to switch tactics (Shuster and Wade 2003). (Tomkins and Hazel 2007) further concluded that mathematical models can neither prove that fitness must be unequal (as was proposed by Gross 1996) nor that fitness must be equal (as was proposed by Shuster and Wade 2003).

## Endocrine Mechanisms of ARTs

The relative plasticity hypothesis (RPH) has been developed to explain the endocrine mechanisms underlying ARTs (Moore 1991). The RPH bases on the theoretical assumption that individuals of one sex that follow ARTs differ in their hormonal mechanisms in a similar way as is observed in primary sex differentiation between males and females (Moore 1991; Moore et al. 1998). Thus, in the same way as males and females differ hormonally, males of different reproductive tactics

are also expected to differ hormonally. Hormones can influence behavior via two main ways (Phoenix et al. 1959): (1) Early in life, hormones can have organizational effects that permanently change the central nervous system and as such adult behavior. Organizational effects are non-reversible. For example, male rodents that experience high levels of testosterone in utero will be more aggressive when being adult. (2) During adulthood, hormones have activational effects, acting on the central nervous system (which was formed via organizational effects during early development), making the expression of specific behaviors more likely. Activational effects are reversible, i.e., when the hormone secretion decrease, the behavior ceases. An example would be singing in song birds, which is activated by testosterone in spring and ceases in summer/autumn when testosterone levels decrease.

The RPH predicts that individuals following fixed ARTS differ in their hormone profiles early in development (organizational effects; Table 1). In contrast, when ARTs are sequential or flexible, individuals following different ARTs are predicted to differ in hormone profiles in adulthood (activational effects; Table 1). The main hormones involved in the regulation of male ARTs are androgens, such as testosterone. Bourgeois males typically have higher androgen levels than other males. Progesterone and glucocorticoids are other hormones that can be involved in the regulation of ARTs. While originally the RPH was formulated

for these steroid hormones only, it is now known that peptide hormones such as prolactin and neuropeptides (oxytocin and vasopressin) can also be involved. Figure 3 shows as an example of how hormone levels differ in male striped mice following ARTs. In this species, it has also been shown that males of the different tactics do not only differ in their endocrine profile but also that individual males change their hormone levels when switching tactics, and that experimental increase of testosterone might induce tactic change. Furthermore, this has consequences for their metabolism, as resting metabolic rate (metabolic rate to maintain basal functions only, measured as oxygen consumption when being at rest at thermo-neutrality) also differs between ARTs.

The endocrinology of ARTs has been investigated in more than 50 vertebrate species, especially in fish and reptiles, but also in birds and mammals, and a role of hormones in regulating ARTs has been reported in nearly every study (reviewed in Oliveira et al. 2008). However, the support for the predictions of the RPH has been low, both for correlative and experimental studies. Oliveira et al. (2008) concluded that the RPH fails to explain a large amount of the observed variation and thus reject the validity of the RPH. Specifically, the existence of hormonal differences in adults of species with fixed ARTs, and an effect of hormone manipulations in adults with fixed ARTs has led to a rejection of the RPH (Oliveira et al. 2008). However, these problems arise mainly

from two facts that should be taken into account when considering the RPH (Table 2): (1) As the RPH is based on the comparison between the male and female sex, it does not predict that males of two fixed ARTs should only differ hormonally during development but not during adulthood. In

the same way, as males and females (fixed reproductive tactics in most vertebrates) differ in their hormonal profile, the same can be expected for two ARTs in one sex. (2) The prediction that hormone manipulations should have an effect in early development in species with fixed ARTs and

an effect in adults of species with plastic ARTs has been interpreted to mean it should otherwise have no effect. However, even in males of species with no ARTs, experimentally administering testosterone can have strong effects, such that the extracted conclusion it should not have an effect in species with fixed ARTs is not understandable. Further, some species with plastic ARTs cannot change their tactic at any stage, but only seasonally, for example, from one breeding season to the next (some blennies, a form of marine fish). Blennies with ARTs do not only show tactic specific behavior but also tactic specific morphology, which is difficult to change. Here, the effect of hormone manipulation might be dependent on the time of year, and experiments done during the breeding season (when the tactic for the season is already fixed) might be less meaningful than in the pre-breeding season. In sum, when taking into account physiological effects resulting from different ARTs and artificial effects that do not imply a natural mechanistic pathway, then the RPH is still highly valuable in understanding the endocrine control of ARTs.

I therefore suggest a modified version of the RPH, which takes two facts into account: (1) Physiological differences are expected in fixed ARTs in adulthood in the same way as hormonal differences are observed between males and females in most species (Table 1). (2) Experimental changes of hormones, potent mediators of physiology and behavior, can cause artificial effects on physiology and behavior that are not observed under natural conditions, as the imposed hormonal changes (for example, artificially high testosterone levels) also do not occur under natural conditions (Table 2).

In sum, the expression of fixed ARTs is regulated by permanent organizational effects during development which can then also lead to permanent differences of hormone profiles in adults. In species with plastic ARTs, the transition from one tactic to another tactic is associated with changes in the hormone profile, representing activational (reversible) endocrine effects. For example, androgen levels typically increase and glucocorticoid levels decrease when males switch from a sneaker to the bourgeois tactic.

## ARTs and Intraspecific Variation in Social Organization

Intraspecific variation in social organization (IVSO) occurs when a species shows two or more of the following forms of social organization: living solitarily, in pairs, one breeding male with several breeding females, one breeding female with several breeding males, or multi-male multi-female groups. Hereby, each form of social organization must be composed of breeding individuals, not only dispersing solitary individuals or bachelor groups. Thus, each sex must have the option to live under alternative forms of social organization. IVSO becomes obvious when individuals of both sexes change their reproductive tactics. In other words, if in one species both males and females can show ARTs, then this can lead to IVSO. For example, the house mouse (*Mus musculus*) can live solitarily, in pairs or in communal groups, with resource availability modifying the intensity of intrasexual aggression in males and female infanticide. In striped mice, both sexes show ARTs, and both sexes can live solitarily or in groups. Thus, solitary living or living in large communally breeding groups consisting of one male and two to four breeding females can occur. In sum, when both males and females show ARTs, both sexes can live in different forms of social organization, which is called intraspecific variation in social organization.

## Conclusion

When different individuals of one sex follow different tactics to reach reproductive success, this represents an interesting phenomenon for all students of animal behavior, both those interested in the evolution and those interested in the physiology and mechanisms of behavior. Such ARTs occur in both sexes though they seem to be more common in males and are clearly understudied in females. ARTs can evolve when either the alternative tactics yield the same average fitness, or if following a suboptimal tactic allows individuals to increase their lifetime reproductive success by having some, even if low, fitness when being

subordinate, waiting to grow and increase competitiveness before adopting the bourgeois tactic with the highest reproductive success. The expression of ARTs is regulated by the endocrine system. Permanent organizational effects (typically early in development) cause fixed tactics, reversible activational effects in adulthood cause switches in plastic tactics. If ARTs occur in both sexes, the social organization of an entire population can change, causing intraspecific variation in social organization. In sum, ARTs represent an interesting phenomenon that allows us to study the proximate causes and ultimate consequences of different behavioral (and sometimes also morphological) phenotypes within one single species.

## Definition

Alternative splicing is the process in which multiple transcripts are generated from a single gene by different combinations of exons of the primary transcript.

## Introduction

In mammalian cells, a diverse array of proteins is generated by the regulation of gene expression at multiple levels including transcription, alternative

splicing, mRNA stability- decay, RNA editing, alternative polyadenylation, proteasomal degradation, and posttranslational modifications. These regulations determine the gene expression outcome. Splicing is the process in which noncoding introns are removed from the primary transcript and coding exons are joined to form functional mRNA. In alternative splicing, by using different splice sites, multiple mRNA and subsequently protein variants are generated from the same gene (Blencowe 2006). From RNA sequencing data, it is now revealed that around 95% of human genes undergo alternative splicing (Pan et al. 2008). The isoforms thus generated have structural variation as well as functional significance. Cells undergo alternative splicing to diversify number of proteins with a limited number of transcribed mRNA (Hartl 2011). About 38,016 distinct mRNA isoforms are generated by the alternative splicing in *Dscam* gene (*Down syndrome cell adhesion molecule*) of *Drosophila melanogaster* (Kalsotra and Cooper 2011; Nilsen and Graveley 2010). Alternative splicing explains the variance between the number of protein-coding genes in the human genome (~30,000) and the different types of proteins that are translated in the human body (~100,000) (Hartl 2011; Keren et al. 2010). Alternative splicing is very frequent in humans while rare in plants. There are many reports of tissue-specific alternative splicing in the case where particular isoform is required for that tissue only (Paterson et al. 2016). Alternative splicing has been postulated in many developmental pathways and disease conditions. Sometimes alternative splicing also leads to premature stop of translation by introducing a stop codon in the middle of the protein-coding mRNA.

## Splicing Machinery

Splicing is carried out by the splicing machinery, i.e., spliceosome which consists core splicing proteins, splicing regulatory factors (SRF), and snRNA (small nuclear RNA). The spliceosomes are directed toward the splice site by some specific

sequence at exon/intron boundaries which is less than 10 bp long. Multiple splice variants are generated by using different splice site in the pre-mRNA.

## Types of Alternative Splicing

There are five basic types of alternative splicing that vary among species (Fig. 1):

- (i) Exon skipping: An exon is either spliced out or retained from the primary transcript. Exon skipping is the most prevalent mode of alternative splicing in the mammalian system which accounts around 40% of alternative splicing event in higher eukaryotes.
- (ii) Alternate 3' splice site selection: When two or more splice sites are present in the downstream exon, only one is selected under specific condition.
- (iii) Alternate 5' splice site selection: When two or more splice sites are present in the upstream exon, only one is selected under a given condition. Splicing through alternate 3' splice site and alternate 5' splice site selection occur, respectively, around 18.4% and 7.9% of total splicing in higher eukaryotes (Keren et al. 2010). This type of splicing introduces little change in final coding sequences.
- (iv) Intron retention: An intron remains in the mature transcript altering the coding potential. It is a very rare event in the animal kingdom but prevalent in plants, fungi, and protozoa.
- (v) Mutually exclusive exons: Usage of the alternative exon in the final transcript.

**Functional Significance of Alternative Splicing:** The conservation of alternative splicing pattern throughout the evolution suggests their strong biological significance. Alternative splicing contributes for the proteome diversity in the cell. Alternative splicing has a central role in maintaining pluripotency of stem cells and also in developmental pathways. The core pluripotency factors

**Alternative Splicing, Fig. 1** Five different types of alternative splicing pattern. Blue, red, violet, and green boxes are exons, blue solid line is representing intron, dashed line

is corresponding to the splice sites. Splice isoform products after alternative splicing are shown on the right

undergo alternative splicing to produce multiple splice isoforms that have roles in the determination of cell state. Many anti- and proapoptotic factors as well as death receptors and caspases are generated through alternative splicing, each with prominent role in biological processes. Splice variants of certain apoptotic genes which are generated by the alternative splicing have the opposite functions. Alternative splicing at the 5' splice site in the first exon of BCL-X and APAF1 gene produces long and short isoforms with anti- and proapoptotic functions, respectively (Boise et al. 1993; Paronetto et al. 2016; Walke and Morgan 2000). The splice isoforms also affect the apoptosis process and immune cell homeostasis. Alternative splicing regulation by splicing regulatory proteins modulates the cell cycle progression along with apoptosis.

## Alternative Splicing and Human Diseases

Aberrant functioning of alternative splicing machinery is well reported in many human diseases as muscular dystrophy, hemophilia, neurodegenerative disorder, cancer, etc. Differential

splicing in the TP53 (tumor suppressor p53) is linked to many neurodegenerative diseases like Alzheimer's and amyotrophic lateral sclerosis (Paronetto et al. 2016). Point mutations in the hereditary diseases affect the alternative splicing and alternative polyadenylation. The deregulation in splicing of cancer-associated gene either by mutations in the splicing regulatory elements or by modulation in the activity of splicing factors implicated in its pathogenesis. The expression of many SR (splicing regulatory) proteins, viz., SRp20, SF2/ASF, and SC35, is upregulated in ovarian, colon, thyroid, kidney, and lung cancers. Regulation of alternative splicing of proto-oncogenes and tumor suppressors modulate their concentration and cellular activity with impact on cancer progression. Abnormal splicing leads to the formation of tumor inducing variants which affect the cell signaling and induce the cell proliferation. Alternative splicing in many cancers either generates active form of proto-oncogene or inactive form of tumor suppressor gene and thus draws the cells toward tumor development and progression. Modulation of splicing process is now a promising therapeutic approach to many human diseases.

## Conclusion

Each type of cell has its own regulatory mechanism of posttranscriptional regulation of gene expression to form the repertoire of proteins of their need in time- and context-specific manner. Metazoan transcriptome analysis uncovered the diversity in mRNA level generated by the alternative splicing. It is tightly regulated process in spatiotemporal manner. It is a means of gene expression regulation which enables a single gene to encode multiple mRNA/protein isoforms. There are five different modes of alternative splicing, viz., exon skipping, alternate 5' splice site, alternate 3' splice site, intron retention, and mutually exclusive exons. Alternative splicing is implicated in the development, pathological diseases, cell cycle, and many other cellular processes. The deregulation in this process and mutation in different splicing factor result in pathogenesis of many diseases.

University of California, Irvine, Irvine, CA, USA

## Synonyms

[Nicolous](#)

## Definition

Animal young that are exceptionally helpless for a short period following birth and require extensive parental investment and care.

## Introduction

Both avian hatchlings and mammal offspring can be classified based on their developmental state at, and shortly following, birth. Young with limited motor functioning and a heavy reliance on parental care are often described as altricial young. In contrast, offspring that are born relatively independent and well-developed are labeled precocial young. These classifications first appeared in the early 1800s through the works of Carl Jakob Sundevall and Lorenz Oken (Starck and Ricklefs

1998). Since then, these labels have been widely adopted to identify the developmental state of avian and mammal offspring at birth, although recent research suggests that this dichotomous rating may not reflect the full range of development found in some families (Starck and Ricklefs 1998). However, within most avian and mammal orders, there are distinct characteristics that identify young as altricial.

### Altricial Aves Young

All birds produce offspring by laying eggs, which are then incubated outside the body. However, the level of embryonic development at which the young fully hatch from the egg can vary, causing both altricial and precocial young. For example, parrot chicks require parental care many months after hatching, while megapode hatchlings can fly within a day of hatching (Starck and Ricklefs 1998). The predominant developmental mode of ancestral birds is difficult to discern based on fossil records, but 8,890 of the 9,993 extant species of birds are classified as having altricial young (Scheiber et al. 2017). Altricial birds tend to be ectothermic for several days after hatching and have small brains, immature muscles, poorly ossified skeletons, a lack of plumage, closed eyes, and increased nest attendance. However, altricial birds make up for this initial immaturity through post-hatching rates of development that are, on average, three to four times faster than precocial bird species.

### Altricial Mammalia Young

It is presumed that ancestral nonhuman mammals produced altricial offspring (Derrickson 1992). However, over the years, nonhuman mammals have developed greater flexibility in developmental mode relative to avian orders. For example, the Carnivora and Rodentia both exhibit a full range of developmental modes, from extremely altricial to fully precocial (Starck and Ricklefs 1998). General characteristics of altricial nonhuman mammals include neonates born in litters, low

birth weight, a lack of body hair at birth, and eyes and ears closed at birth. In addition, altricial nonhuman mammals have gestational periods that are, on average, a third the length of precocial nonhuman mammals. The two developmental modes differ greatly in brain size at birth as well; adult altricial mammals typically have brains 7.5 times larger than their neonates, compared to precocial adults, which have brains only 2.5 times larger than precocial neonates (Martin 2007). To account for this variability in brain size at birth, rapid brain growth in altricial nonhuman mammals often continues for days or weeks after birth before stagnating. In contrast, rapid brain growth slows at or near the time of birth for precocial nonhuman mammals. It is within this aspect of postnatal growth that human infants, who continue to experience rapid brain growth for a year after birth, deviate from other mammals.

Humans are often classified as being secondarily altricial. That is to say that while human infants share many characteristics with their precocial relatives, they are also born quite helpless, like altricial young. It is believed that human ancestors initially gave birth to precocial young given that modern humans usually produce single, well-developed neonates with eyes and ears open after a lengthy 38-week gestation. For comparison, chimpanzees have an average gestation of 32 weeks, gorillas 37 weeks. In addition, the nutritional composition of human breast milk is remarkably similar to that of other precocial primates (Rosenberg and Trevathan 2002). Yet, human infants are born with their motor skills significantly underdeveloped and have the latest maturity patterns of any primate. As a result, human infants clearly rely heavily on their caretakers for survival and are therefore, also altricial.

### Selective Pressures for Altricial Young

The leading explanation for this paradox is described by the hypothesized obstetrical dilemma. Approximately 3 million years ago (mya), most likely within the genus *Australopithecus*, hominids developed bipedalism, or the ability to traverse on two rear limbs. The exact

selective pressures that resulted in this change are still unclear, but skeletal records indicate that the adjustment resulted in the development of a vertically oriented pelvis (Weiner et al. 2008). This transformation, in turn, significantly narrowed the human birth canal. This narrowing did not initially present a dilemma, as the average brain size was only 400 mL, compared to the present day 1,300–1,500 mL (Weiner et al. 2008). However, hominids eventually experienced encephalization around 2–2.5 mya, with brain size almost tripling between the *Australopithecus* and *Homo sapiens*. This extreme growth resulted in increasingly difficult birth scenarios, as infants struggled to fit through the narrowed birth canal. As such, strong selective pressures existed for infants to be born earlier in the prenatal period, while the brain is still relatively small and underdeveloped. These pressures came to fruition around 1.6–1.8 mya and resulted in a shortened gestational period within the *Homo erectus* species (Rosenberg and Trevathan 2002). Given that this change shortened prenatal growth, human infants were born rather physically underdeveloped relative to other primates. This modification has persisted since, resulting in the many altricial characteristics, as well as the unique postnatal rapid brain growth, we observe in modern human infants.

For nonhuman animals, the factors that inform the pace of infant development are somewhat less clear-cut. Generally speaking, the theory of evolution suggests that the success of an organism is measured by reproductive fitness. As such, traits are naturally selected for if they increase the number of offspring an organism is able to leave behind. Because all species have unique life histories based on habitat stability, mortality rate, etc., different traits can encourage drastically different effects across species. In other words, the same trait can increase reproductive fitness in one species, while lowering fitness in another. This variation in outcomes results in a pattern of differential selection for traits across species.

Selection for developmental states generally follows this same principle in birds and nonhuman mammals. If the offspring of a species is likely to reach sexual maturity, the species will usually have precocial young. Compared to altricial

young, precocial young requires less parental investment, requires less energy to develop and spend less time vulnerable to predation and adverse climate characteristics. However, a life history of increased mortality or a fluctuating environment may significantly decrease the probability that offspring reach sexual maturity. In these instances, selection pressures may bypass the advantages of having precocial young in an effort to increase reproductive rates via larger litters, shorter gestation, and shorter interbirth intervals (Pagel and Harvey 1988). Thus, some animals give birth to altricial young. For example, animals with unstable access to resources tend to favor giving birth to several altricial young, as this strategy increases the probability that at least one offspring will survive to reproductive age. Similarly, small mammals often favor high reproductive rates and altricial young, as they tend to have higher mortality rates relative to larger mammals. In the end, selection of developmental states results from a strenuous cost–benefit analysis that is unique to each species (Ricklefs 1969).

### Broader Impact of Altricial Young

Given that many environmental pressures shape whether a species has altricial or precocial young, it is not surprising that the developmental state of an infant can, in turn, impact other aspects of animal behavior. For instance, altricial young greatly increase the amount of maternal investment required and provide an opportunity for males to paternally invest in their offspring. For females, increased parental investment means a decrease in the ability to forage and provide for oneself after giving birth. As such, females with highly altricial young must rely on others to provide for them. This creates an opportunity for an infant's father to expand his paternal investment. With vulnerable, altricial young, offspring well-being is intrinsically tied to maternal well-being. As such, males may feel an increased pressure to provide for the mother of their offspring, so as to further the chances that their offspring will reach sexual maturity. These dual motivations, along with other factors such as concealed ovulation, ultimately encourage a shift towards

monogamous relationships; males do not want to invest in a mother if the offspring may not genetically be theirs, while females do not want to commit to raising a child if they will be abandoned. The best way to insure these respective desires is through sexual monogamy, and indeed, research suggests that mammals with monogamous mating systems tend to produce altricial offspring (Benshoof and Thornhill 1979).

Monogamy also requires some level of cooperation. Research suggests that approximately 1.8 mya, around the time changes in human gestation were believed to have occurred, hominid societies shifted from competition towards increased cooperation and sociality. It is likely that this shift can be partially attributed to the shared parental investment required to raise altricial young (Naccache 2012). Shared parental investment and monogamous relationships both require sustained collaborative interactions. As such, the introduction of altricial young may have served as a catalyst for the gradual increase in the complexity of social relationships found in many monogamous populations.

## Conclusion

Within the Mammalia and Aves classes, young come into the world with a vast range of abilities and competencies. The term altricial is used to describe young that fall on the underdeveloped end of this spectrum. These offspring are born with unique deficits that contribute to their helplessness and increase the need for parental care. While this care can be costly, some species may benefit from having altricial young when faced with certain environmental and biological pressures.

## Altruism

Chana K. Akins

Department of Psychology, University of Kentucky, Lexington, KY, USA

## Origins of Altruism

The earliest conceptualization of altruism can be traced back to the Ancient Greeks and

forward to more contemporary behaviorists (Rushton and Sorrentino 1981 for review). The first view was from some of the writers of the old and new testaments and Freud who thought of human nature as essentially bad. A second view was popular among Socrates, Aristotle, and Carl Rogers, who thought of human nature as essentially moral and altruistic. The third view was commonly held by Plato, Locke, Watson, and Skinner who believed that human nature was neutral.

The term “altruism” was coined by French sociologist Auguste Comte (1858) in a description of his ethical doctrine indicating that individuals had a moral obligation to renounce self-interest and love for all others. Not long after Comte coined the term altruism, Darwin published his *Descent of Man* (1871), in which he proposed that humans are biologically disposed to behave socially, cooperatively, and helpful to one another. He speculated that it was “moral sense” that distinguished humans most from nonhuman animals, and it was composed of intellectual power and sociability. Interestingly, while Darwin described examples of altruism in nonhuman animal species, he identified a paradox in the way altruism evolved in natural selection. Specifically, he noted that, if the most altruistic members of a group were willing to die for others, sacrificing themselves, there would be fewer offspring of altruistic individuals to pass on the altruism trait.

Around the mid-1960s, in his book entitled *Animal Dispersion in Relation to Social Behavior*, Wynne-Edwards suggested that evolution occurred through group selection, at the level of the species (Wynne-Edwards 1962). He argued that many behaviors evolved for the good of the species as a whole, rather than at a lower level of organization. His arguments were strongly criticized by George C. Williams, an evolutionary biologist, in *Adaptation and Natural Selection* (Williams 1966), in which he argued on the basis of mathematical models that individuals would not altruistically sacrifice fitness for the sake of a group. He persuaded the majority of biologists that group

selection did not occur, other than in special situations such as the haplodiploid social insects like honeybees (Hymenoptera), where kin selection was possible. To support his stance, Williams used the popular lemming example, in which some lemmings take it upon themselves to commit suicide to relieve pressure on critical food resources. The classic scenario is one in which a population of lemmings is jumping off a cliff into treacherous water on a suicide mission but one individual wears a life preserver around its waist. In such a case, group selection would be said to favor the allele(s) for suicidal behavior. However, Williams argued that altruism could not have evolved through group selection because selection among individuals will usually have a stronger effect than group selection in shaping the genetic makeup of the population. Additionally, he argued that groups of altruists would have to prevail over groups of selfish individuals at a faster rate than the selfish individuals within the groups and group selection is much slower than individual selection.

## Types of Altruism

### Hamiltonian Altruism and Kin Selection

Charles Darwin discussed the concept of kin selection in his 1859 book, *The Origin of Species* in which he questions the altruistic behavior of sterile social insects, such as honeybees who leave reproduction to their mothers. He also describes how populations evolve across many generations through natural selection. Under natural selection, a gene encoding a trait that enhances the fitness of each individual carrying it, should increase in frequency within the population, and conversely, a gene that lowers the individual fitness of its carriers, should be eliminated. A gene that prompts behavior that enhances fitness of relatives but lowers the individual carrying it, should increase in frequency within a population because relatives often carry the same gene. The enhanced fitness of relatives would more than compensate for the fitness loss incurred by the individuals, making kin selection possible. In 1975, Harvard

biologist, E.O. Wilson published *Sociobiology*, which re-launched the debate about nurture versus nature and proposed that social behavior, such as altruism was often genetically programmed and that these genes were subject to natural selection. Relatively recently, Wilson recanted this explanation for altruism (discussed below and Nowak et al. 2010).

Maynard Smith (1964) coined the term “kin selection” to describe how helping relatives to reproduce resulted in indirect fitness benefits, the reproduction of nondescendent kin. Hamilton (1964) described kin selection more specifically stating that because genetically related individuals were likely to carry the copies of the same alleles, they would be more likely to help their kin to ensure that copies of their alleles were passed on. The prominent biologist, J. B. S. Haldane (1932) popularized the math involved in kin selection by stating that he was willing to lay down his life for two brothers or eight cousins. It was Hamilton who later expressed the conditions under which such altruism would evolve through the following equation:  $r \times b > c$  where  $r$  denotes the relatedness of the individuals,  $b$  denotes the benefit to the recipient of the altruistic act, and  $c$  denotes the cost to the altruist (Hamilton 1964). The equation predicts that altruistic behavior would more likely occur among individuals that are closely related kin. Cooperation is favored by natural selection if relatedness is greater than the cost to benefit ratio. Hamilton also coined the term “inclusive fitness” to refer to the total genetic success of an individual based on personal reproduction (direct fitness) and the effects on reproduction of nondescendent kin (indirect fitness). Inclusive fitness is a defining feature of kin selection.

#### Examples of Kin Selection

One popular example of kin selection is in the Polistes, paper wasp (Hamilton 1964). The female wasps mate with unrelated male wasps during the breeding season and then spend the winter hibernating in a shelter. In the spring, they emerge and start a nest that contains a single egg. Other females join the foundress

female and a hierarchy is established. The dominant female reproduces and the subordinates help rear the larvae and protect the nest against predators and parasites. The queen wasp uses sperm stored from last fall’s copulation to fertilize the eggs that were laid early in the season. These eggs are destined to become daughters. When it is adaptive to produce sons, she lays unfertilized eggs.

When the first females emerge, they help their mother raise more daughters (both full and half sister) rather than fly off and start their own colonies. The queen continues to produce more eggs. As summer progresses, some of the females that the queen produces, stop working and start taking food from their sisters. Later, males emerge for the first time and they also do nothing to help the colony. The latter females and males fly off together and mate, the males die, and the females hibernate through the winter to start the cycle all over again.

The daughters of the queen wasp serve in helper roles for life because they may not have the option to reproduce and by helping their sisters such that they increase their fitness indirectly. Females and males who do not take on the helper role may be acting to increase their fitness directly by increasing their personal chance of reproductive success.

Another example of kin selection is in the Belding’s ground squirrels. These squirrels produce a whistle-like alarm call when they see a terrestrial predator, such as a coyote or badger. Paul Sherman (1985) observed predators capture and kill alarm callers at a higher rate than non-calling, fleeing squirrels and investigated the mechanisms underlying the alarm calling. He found that the caller may serve to enhance its own personal chances of reproductive success by alerting its neighbors so that together they create a chaotic mass that confuses the predator and allows them to run away safely. But in addition, while the caller may reduce its chances for reproductive success, it increases its inclusive fitness by alerting its relatives. Females are more likely to give calls than males. They may be increasing the chances of survival of their offspring but also because females live with

many relatives compared to more solitary males, females could be increasing the survival of their relatives. Females with living relatives nearby call more frequently than females without living relatives as neighbors.

Evidence of gene bias in humans is suggested by the phenomenon of mother's brother (Alexander 1974). The phenomenon suggests that if a man lacks confidence in his paternity of his children, his nieces and nephews may become his closest relatives in the next generation. According to Alexander, lowered confidence in paternity may be caused by circumstances that involve husbands and wives living apart and/or long absences of husbands on hunting or military trips. Low confidence may lead to reduced paternal care by the mother's spouse, thus increasing the value of care given by the mother's brother. Mathematically, when a man can only estimate his paternity at 25% or lower, he becomes the most closely related male to the sister's offspring. Thus, in accordance with kin selection, preferential care may be given to those most genetically close to us but if the genetic components are questionable, the altruist may find the next closely related non-descendent kin to invest in. Evidence for the mother's brother's phenomenon is rare but is thought to occur in polygamous societies where confidence of paternity is relatively low.

Recent research on inclusive fitness and cooperation among kin shows that human kin selection may not only include genetic kin but also kin by marriage (in-laws) (Dyble et al. 2018). Unrelated kin and spouses may not necessarily share genes but they may have shared genetic interests in future reproduction, and therefore, may derive indirect fitness benefits through cooperating. For example, a mother may have an interest in the reproduction of her son's wife. Dyble and colleagues (2018) used a standard inclusive fitness theory to calculate a coefficient of shared reproductive interest that predicts altruism in both genetic kin and in-laws. The researchers concluded that "two-daughters-in-law or eight cousin's spouses" could be added to the inclusive fitness statement of saving two brothers and eight cousins.

## A Recent Debate about Kin Selection

For decades, many scientists have accepted the notion of kin selection which is based on inclusive fitness, genetic success based on personal reproduction (direct fitness), and effects on reproduction of nondescendent kin (indirect fitness). The prominent biologist E.O. Wilson was a strong proponent of kin selection, especially in explaining the behavior of social groups of animals such as bees, ants, and termites. Recently, E.O. Wilson, Martin Nowak, a Professor of mathematics, and Benjamin Allen, a Research Associate in mathematical biology, rejected this notion and have determined that the theory is mathematically flawed (Nowak et al. 2010). They point out that a large majority of the field data does not fit with the predictions of kin selection theory. They found that cooperation was common among many species where individuals were not genetically related and many instances where cooperation was not found within species, even though the mathematics of kin selection theory would predict it. Rather than kin selection, Wilson and colleagues (Nowak et al. 2010) suggest a mathematical model for the evolution of eusociality (sociality that involves cooperative brood care, overlapping generations within a colony, and a division of labor of reproductive and non-reproductive groups). The model does not require individuals to be related to others' offspring. There continue to be many defenders of the original kin selection theory.

## Reciprocal Altruism

In *The Evolution of Reciprocal Altruism*, Trivers (1971) discusses a different type of altruism than Hamilton suggested. In this entry, he describes how it pays off for individuals to render assistance to others when the cost is low and if, in doing so, it increases the probability of receiving help of greater value in the future. Trivers (1971) describes several conditions that favor the evolution of reciprocal altruism including: (1) a long life span of individuals of a species to maximize the chance for altruistic acts to occur, (2) low dispersal rate to increase the likelihood of interactions between the same

neighbors, and (3) interdependence of members of a species to keep individuals near each other. Trivers also mentions that while parental care, mutual dependence between parents and offspring, can be explained by Hamilton's model (Hamilton 1964), there is no reason that reciprocal altruism may not also operate between close kin. He also points out that these are broad conditions that favor reciprocal altruism but how many altruistic acts occur and the symmetry of those interactions are the most important parameters.

In his original description of reciprocal altruism, Trivers (1971) interpreted cooperative interactions between members of different species as reciprocal exchanges of assistance and pointed out their similarity to the Prisoner's Dilemma game (Axelrod and Hamilton 1981). In the Prisoner's dilemma, two individuals can each either cooperate or defect. No matter what the other does, defection yields a higher payoff than cooperation. If they both defect, both do worse than if both had cooperated. If the game is played long enough, it becomes an iterated version in which strategy can be used to determine the probability of cooperation and defection as a function of history. Among a huge number of reciprocal strategies, tit for tat is one of the most simplest ones. It is based on two simple rules: to cooperate in the first trial and, in the following, to do what the other player (opponent) did in the last trial. Under certain constraints, mutual cooperation appears to be the best strategy whenever reciprocity is maintained.

### Examples of Reciprocal Altruism

It has been suggested that altruistic acts performed between two individuals from different species may be the purest form of reciprocal altruism because there should not be any genetic enhancement from the altruistic act (Rothstein 1980). Some species interact with other species in a symbiotic relationship in which both groups have mutual dependency. For example, a large number of fish and shrimp are known to be cleaners of other larger species of fish (Feder 1966). Cleaner fish and shrimp rid host fish of ectoparasites by entering the gill or the mouth

of the host fish and ingesting the parasites. Cleaner fish and shrimp are distinctly colored and behave in distinct ways (i.e., dipping and rising movements) to attract host fish to be cleaned and inhibit other fish from eating them. According to Feder (1966), there is likely a strong selection for hosts not to harm their cleaners and, as predicted, there are species that mimic cleaners in similar colors and movements but then attempt to take a bite out of the fish approaching to be cleaned.

A host fish to be cleaned seems to perform several altruistic acts. First, it avoids eating the cleaner, even though natural selection should favor a cleaning followed by a good meal. Second, it signals to its cleaner when it is about to depart, and third, it may chase off other fish that pose a danger to the cleaner.

The behavior of the host fish may have resulted from natural selection because of the benefits of keeping the cleaner alive (Trivers 1971). To support the hypothesis that the host is repaid its initial altruism, Trivers (1971) presented several conditions favoring the evolution of reciprocal altruism. First, the host actually suffers from these parasites. Research has shown that the removal of all cleaner fish from a coral reef drastically reduces the number of larger fish within the next few days. Additionally, many of these territorial fish develop swellings, white fuzzy blotches and ulcerated sores. Secondly, finding a cleaner is difficult and dangerous. Observations show that if cleaners do not appear over one coral in about half a minute, host fish swim to another coral and wait. Thus, there may be several alternative cleaning stations to go to. In addition, it may be dangerous for some fish to be cleaned because they have to leave their protective environments. For example, moray eels do not normally leave their holes during the day time but they will in order to be cleaned. A third piece of evidence suggesting that the host is reciprocating its cleaner is that there is site specificity. Feder (1966) reviewed evidence for this, concluding that cleaner fish have regular stations to which fish wanting to be cleaned can go. This is especially evident of territorial recipients of the

cleaner. Fourth, the lifespan of the cleaner seems to be easily long enough for effective selection against cheaters. And lastly, it is been shown that hosts use the same cleaner repeatedly. All of this evidence suggests that the cleaner organisms and their hosts meet the conditions for the evolution of reciprocally altruistic behavior.

Another example examined by Trivers (1971) is the warning calls in birds. Warning calls in birds do not allow for the predator to easily determine the location of the call giver. However, giving a call may occasionally result in the death of the caller, either by the observing nearby predator or a second nearby predator. Trivers (1971) suggests that the calls are selected for because they aid the bird that gives the call. It is disadvantageous for an observer bird to have a predator eat a nearby conspecific or fellow bird because the predator may then be more likely to eat the observer bird. Thus, giving a warning call prevents predators from specializing on the caller's species which includes forming a specific search for the prey species, learning the habits of the species, and perfecting its catching techniques on it. Second, the warning call prevents predators from specializing on the species locality which includes frequenting the area where the birds live and learning useful information about the area in which the bird lives. According to Trivers (1971), it does not matter if the calling bird may be helping its non-neighbors more than it is helping itself. What counts is that it outcompetes conspecifics in areas where no one is calling. The noncalling neighbors will find themselves in an area without any caller and will be selected against relative to birds in an area with callers.

There is no evidence that the birds can discriminate against cheaters but there is also no evidence that the birds stop giving calls because their neighbors are not reciprocating. It seems that just the fact that the neighbor survives repays the caller of its own altruism.

In humans, sperm donation in the USA may be an example of reciprocal altruistic behavior. European and Australian investigators contend that sperm donation is primarily altruistic and

that financial motives are strictly secondary. Although in these communities, financial compensation is often withheld and yet recruitment remains successful. However, in the USA, the donor is usually paid for services rendered and without compensation, recruitment may be challenging. In a study by Rushton et al. (1981), 42 male sperm donors who were active in an insemination program were surveyed along with 50 male matched controls (note that the only difference is that they did not donate). Both donor and control groups opposed contact between offspring and donor and donors demonstrated little interest in meeting the recipients. Sixty-two percent of the donors surveyed said that money was the primary reason for participating. Thirty-six percent said that they would like to see the child and only 36% would inform their wife or partner. Two major differences in the motivation of donors versus controls were that controls were more in agreement than donors that donating sperm was altruistic. However, donors were in more agreement than controls that donating sperm was more like donating blood. In this survey, money was clearly the primary reason for donor participation. The majority of respondents would not participate if money was withheld. Furthermore, both donor and control groups favored financial compensation for participants. According to Rushton and colleagues (1981), sperm donors in the USA donate sperm based on reciprocal altruism.

A more recent study investigated the effect of reciprocity priming on organ donor registration intentions and behavior (O'Carroll et al. 2017). In Study 1, participants who were not currently registered organ donors took part either face-to-face or online and were randomly allocated to a reciprocity-prime or control condition. Primed participants were required to respond on a 7-point Likert scale from "*Strongly disagree*" to "*Strongly agree*," to the item "*I would accept an organ from a deceased donor in order to save my own life.*" The control item was "*Organ donation is important,*" and participants responded on the same 7-point scale. Following the manipulation, they were asked

to indicate, on either a paper or online questionnaire, their intention to join the organ donor register. Study 2 was similar to Study 1 but with the addition that after reporting intention, participants were then offered an organ donation information leaflet or the opportunity to click a link for further information (proxy behavioral measure). The results of both studies showed that reciprocity-primed participants reported greater intentions to register than controls. However, in the second study, there was no evidence of donation behavior. The findings showed that using reciprocity might be an effective tool to increase individuals' intentions of organ donor registration but this increase in intention may not translate into donation behavior.

### **Does Reciprocal Altruism Exist in Nonhuman Species?**

While there are numerous examples of what appears to be reciprocal altruism in nonhuman species, some scientists question whether cooperation among nonhuman species truly represents reciprocal altruism or whether it is limited to strategies that generate immediate fitness benefits (e.g., Clutton-Brock 2009). Although experimental studies with captive birds and mammals have shown that the probability that individuals will assist each other can be affected by the previous behavior of partners or other group members, very few attempts have been made to measure the net fitness benefits of reciprocal altruism between non-kin. Only a few of the studies commonly cited as examples of direct reciprocity in natural populations provide evidence that definitively excludes the possibility that cooperative behavior is maintained by immediate shared benefits, manipulative tactics, or kin selection.

Not only might there be alternative possible explanations for most examples of reciprocal altruism in nonhuman species but reciprocal exchanges can be costly, resources highly valuable, there can be considerable delays between giving, and extensive opportunities for cheating. Clutton-Brock (2009) suggests that reciprocal exchanges might also require some form of language to establish expectations and intentions,

to take into account the timing of exchanges, and to establish social norms to discourage cheating.

### **A Critique of Reciprocal and Genetic Altruism: Are They Really Separable?**

Reciprocal altruism and kin selection (genetic altruism) may not be clearly separable phenomena as they are currently defined. Reciprocal altruism is an exchange of favors between nonrelatives in which the giving and returning of favors occurs at different times and in which the cost of providing favors are lower than the benefits receiving them (Trivers 1971). Kin selection takes place when individuals increase their inclusive fitness by helping other individuals (usually closely related) who share the genes responsible for their aid giving behavior. Rothstein (1980) suggests that most examples of reciprocal altruism are special cases of kin selection. According to him, when conspecific reciprocal altruists exchange favors they are almost certainly doing so because they share at least some of genes responsible for their altruism. Therefore, the only type of reciprocal altruism that is distinguishable from kin selection is reciprocity between members of different species, such as the cleaner fish (Trivers 1971) described earlier. Because there are very few examples of interspecies cooperation, according to Rothstein (1980), there is generally always some genetic similarity among altruists and therefore, pure reciprocal altruism rarely exists and thus individuals who engage in reciprocal altruism are to some extent kin.

### **True Altruism and Ascetic Altruism**

#### **Conceptualizations**

There have been numerous attempts to conceptualize and explain true altruism. Simon's model (e.g., Simon 1990) suggests that, even if genes are the controlling sites of natural selection, people have the capacity to learn at the socioeconomic level which can lead to the selection of altruism. According to Simon (1990), docility is the basis for true altruism and true altruism

is a by-product of docility. Docility refers to the capacity for being instructed and the tendency to accept and believe those instructions. Docile individuals are those who are adept at social learning and who accept well the instruction society provides for them. These individuals tend to learn and believe what they perceive others in the society want them to learn and believe. Simon's model (1990) suggests that docile persons are more than compensated for their altruism by the knowledge and skills they acquire. A critical assumption of the model is that social organizations know better than individuals. That is, social organizations help structure the information that flows among individuals to improve their individual fitness. Thus, rather than function as independent individuals, there may be an accumulation of knowledge that gives each member of the group a fitness advantage.

Hoffman (1981) offers four kinds of behavioral evidence for biologically based altruism: (1) people frequently help others in society, (2) that a great deal of helping is performed by those whose needs for approval is not strong, (3) it often occurs almost immediately, and (4) that signs of relief in others appear to reinforce helping behaviors. Hoffman also suggests that natural selection requires a system that is reliable and yet also flexible and what therefore must have been acquired is a predisposition or a motive to help. And although this may be biologically based, it is nevertheless amenable to control by cognitive processes.

Another attempt at explaining true altruism has been to involve the construct of empathy. Aronfreed (1972) accounted for both the origin of empathy and the capacity of emphatic reactions to produce altruistic behavior. He observed that small children learn to feel bad when others feel bad and they learn to feel good when others feel good early in their lives because these conditions serve as conditioned stimuli, which through associations come to evoke similar affective responses. The motivation behind empathy is to relieve distress, which we supposedly feel when we see someone else suffering. Relieving one's own distress may appear to be a

selfish act but Hoffman (1981) argues that although the consequence of helping reduces the helper's distress, there is evidence that the conscious intention of helpers is to reduce the distress of another. In addition, he suggests that since motives are always accompanied by feelings of satisfaction, a feeling of satisfaction cannot be used to distinguish between egoist and altruistic motives.

Mary Maxwell discusses her conceptualization of true altruism in her book *Morality Among Nations: An Evolutionary View* (Maxwell 1990). In it, she proposes that reciprocal altruism led to the development of moral emotions (which she credits as Triver's idea). Moral emotions cause the development of notions of right and wrong. Notions of right and wrong result in the institutionalization of morality in human society. She believes it is faulty logic to state that natural selection requires altruism to be selfish and therefore all altruism is selfish. Rather, she contends that humans have entered into a "new human-created environment" in which mortality has different ways of controlling behavior and motives.

Joseph Lopreato defines true or ascetic altruism as behavior, conscious or unconscious which, guided by innate predispositions, potentially reduces the inclusive fitness of the benefactor while increasing that of the beneficiary (Lopreato 1981). In his article on *Genuine Altruism in Homo sapiens*, he attempts to search for and explain altruism as behavior that reduces the inclusive fitness of the giver while increasing that of the recipient. He refers to altruism as "ascetic altruism" because of the ambiguity with use of the term "altruism" and to include the concept of self-denial that is included in the concept of asceticism.

According to Lopreato (1984), true altruism evolved as a result of an increase in complexity of society or groups. Social pressures and demands of society (to help when needed) increased as the complexity of groups increased. However, as the selfish gene theory (Dawkins 1976) professes, we are internally driven to maximize our own genetic fitness. The drive to fulfill our social demands conflicts with our drive

for genetic fitness. This opposition causes dissonance that ultimately causes shame. In order to rid ourselves of this dissonance and shame, we gain souls or moralistic behavior. The soul allows us to be truly altruistic. As groups become more complex and increasingly demanding, the hierarchy of altruism would consist of true altruism at the top existing in groups with high socialization and complex interactions. At the bottom of the hierarchy would be genetic altruism existing in groups with very little social interaction and dependency. And reciprocal altruism should fall in the middle.

The evolution of the soul is a by-product of self-deception whose main effect was and may still be the maximization of inclusive fitness (Lopreato 1984). Self-deception may have evolved from increasing complexity of the reciprocal system and as a means of coping with flagrant cheating of an evolving dominance order. As long as self-deception and the idea of soul exist, a certain percentage of individuals are likely to fall victims to them.

### Does True Altruism Exist?

The ultimate question about true altruism is whether it exists such that people do things for each other without expecting something in return.

Several studies report physical and psychological benefits associated with altruistic behavior. For example, volunteerism is positively correlated with self-reported happiness, health, and well-being (see Filkowski et al. 2016 for review). People who regularly volunteer report greater satisfaction in life and exhibit reduced rates of depression and anxiety compared to those who do not volunteer. Similarly, engaging in acts of kindness has also been associated with increased well-being. These findings indicate that being aware of the kindness of others and of one's own acts of kindness is related to increased self-reported levels of well-being. In a study by Otake et al. (2006), participants were asked to count the number of acts of kindness they performed for 1 week. A control condition did not partake in the "counting kindness" task. Results indicated that counting acts

of kindness significantly increased self-report levels of happiness. Together, these studies suggest that altruistic behaviors not only benefit others but also have profound positive effects on the current and future physical and psychological well-being of the person performing the behavior.

Lopreato (1981) describes a discussion involving the sociobiologist E.O. Wilson, about whether Mother Theresa is an example of ascetic or true altruism. Mother Theresa was a member of the Missionaries of Charity and therefore nonreproductive. In Calcutta and elsewhere, she cared for poor, the forsaken, the sick, and the foundlings. She received international honor and recognition, including the 1979 Nobel Peace Prize. E.O. Wilson notes that even Mother Theresa is selfish, "for she seeks to save her soul" (cited in Lopreato 1981). Lopreato (1981) suggests that the sociobiology of altruism concerns the salvation of genes and not souls and therefore Mother Theresa is a true altruist and there may be others like her. She sacrificed her reproductive fitness in the service of countless individuals who are unrelated to her.

## Amino Acid

Akanksha Kushwaha  
Department of Zoology, Banaras Hindu  
University, Varanasi, India

## Definition

Amino acids are compounds containing an amino group, a carboxyl group, a hydrogen atom, and a distinctive side chain, all bonded to a carbon atom, the  $\alpha$ -carbon.

## Introduction

Amino acids serve as monomer of proteins. Amino acid residues are covalently linked through peptide bond to form a protein. Twenty different amino acids are commonly found in proteins. The first discovered amino acid was asparagine. All amino acids have trivial or common names, in some cases derived from the source from which they were first isolated. Asparagine was first found in asparagus, hence the name asparagine (Vauquelin et al. 1806). All amino acids except glycine are optically active, i.e., they rotate the plane of polarized light.

In an amino acid, if the amino group and carboxylate groups are attached to the same carbon atom, which is called  $\alpha$ -carbon, then the amino acid is called  $\alpha$ -amino acid. Various  $\alpha$ -amino acids differ with respect to the side chain attached to their  $\alpha$ -carbon. The general structure of an amino acid is:

The R group or side chain attached to the  $\alpha$ -carbon is different in each amino acid.

Many naturally occurring amino acids which are not found in proteins have structures that differ from the  $\alpha$ -amino acids. In these compounds the amino group is attached to a carbon atom other than the  $\alpha$ -carbon atom, and they are called  $\beta$ -,  $\gamma$ -,  $\delta$ -, or  $\epsilon$ -amino acids depending upon the location of the C-atom to which amino group is attached. For example, GABA (gamma-amino-butyric acid) is a  $\gamma$ -amino acid, and  $\beta$ -alanine is a  $\beta$ -amino acid (Nelson et al. 2005).

Amino acids exist in solution as the dipolar ion or zwitterion. A zwitterion can act as either an acid or a base. Hence, an amino acid is an amphoteric molecule. Because amino acids contain ionizable

groups, the predominant ionic form of these molecules in solution depends on the pH. Titration of an amino acid illustrates the effect of pH on amino acid structure. The pH at which an amino acid has no net charge and is electrically neutral is called its isoelectric point (pI).

## Classification of Amino Acids

I. Classification based on nature of R group: This classification is based on the properties of R groups, in particular, their polarity or tendency to interact with water at biological pH.

1. *Nonpolar, aliphatic R groups*: glycine, alanine, proline, valine, leucine, isoleucine, methionine
2. *Aromatic R groups*: phenylalanine, tyrosine, tryptophan
3. *Polar, uncharged R groups*: serine, threonine, cysteine, asparagine, glutamine.
4. *Positively charged R groups*: lysine, histidine, arginine
5. *Negatively charged R groups*: aspartate, glutamate

II. *Classification based on dietary requirement of amino acids*: Living organisms differ in their capacity to synthesize the amino acids required for protein synthesis. Many microbes can produce all 20 standard amino acids from readily available precursors, but other organisms must obtain some preformed amino acids from their diet. Mammals and other animals can only synthesize a subset of these standard amino acids, known as the 12 nonessential amino acids. The remaining eight essential amino acids must be obtained from the diet:

1. *Essential amino acids*: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine (arginine and histidine are essential for infants)
2. *Nonessential amino acids*: alanine, proline, asparagine, aspartate, cysteine, glutamate, glutamine, glycine, serine, tyrosine

## Standard and Nonstandard Amino Acids

More than 300 amino acids are present in cells; however, only 22 amino acids participate in protein synthesis ribosomically. Such amino acids are called proteinogenic or standard amino acids. Apart from the 22 standard amino acids, all other

amino acids which are not ribosomically incorporated into proteins are called nonstandard amino acids. In addition to the standard amino acids, some proteins may contain nonstandard amino acid residues formed by posttranslational modification of standard amino acid residues already incorporated into a polypeptide. These modifications are often essential for the function or regulation of a protein. Examples of such amino acids are 4-hydroxyproline, desmosine, and N-acetylserine (Ambrogelly et al. 2007).

## Amniocentesis

Vidya Shukla  
Brain Research Laboratory, Biotechnology Unit,  
Department of Biosciences, Mangalore  
University, Mangalore, Karnataka, India

## Synonyms

[Amniotic fluid test \(AFT\)](#)

## Definition

Amniocentesis, also called as Amniotic Fluid Test (AFT), is an invasive prenatal medical procedure

carried out primarily to diagnose chromosomal abnormalities and/or infections by using fetal DNA from the cells collected from the amniotic fluid.

## Introduction

In 1956, American obstetrician Fritz Friedrich Fuchs and Danish gastroenterologist Polv Riis pioneered the technique of Amniocentesis by collecting samples to determine the fetal sex. Up until the 1970s amniotic fluid collection was done blind. In 1972, Jens Bang and Allen Northend reported that needle insertion for amniotic fluid collection could be done using ultrasound techniques.

Amniocentesis is usually reserved for those women considered at higher risk of carrying a fetus with a chromosomal or genetic abnormality. In most cases, the women are suggested to undergo amniocentesis only after genetic counseling to avoid miscarriage as a result of amniocentesis.

## General Description

The fetal programming hypothesis proposes that the in utero environment can impair fetal development, with a permanent effect on the phenotype. Amniocentesis is one of the techniques used to assess and predict the possible phenotypic or genotypic deformities. It is mainly of two types – early amniocentesis and second trimester amniocentesis, also called as late amniocentesis. The major difference between the two is the amount of amniotic fluid aspirated and the gestation period during which sampling is carried out. During early amniocentesis about 10–12 ml of fluid is collected from the amniotic sac, and sampling is done between 11–13 weeks of gestation whereas in late amniocentesis, which is carried out during 16th week of gestation period, up to 20 ml of sample can be extracted (A thumb rule suggests that not more than approximately 1 ml per week of gestation be extracted). Complications post procedure may include amniotic fluid leakage, pregnancy loss, preterm labor and delivery, respiratory distress, postural deformities, chorioamnionitis,

fetal trauma, and alloimmunization of the mother (rhesus disease). Some of the most common abnormalities detected are Down syndrome (trisomy 21), Edwards syndrome (trisomy 18), Patau syndrome (trisomy 13), and Turner syndrome (monosomy X) (Alfirevic et al. 2003; Ogilvie and Akolekar 2014).

The procedure is performed with uninterrupted ultrasound guidance under the influence of local anesthesia. A sterilized 22-gauge spinal needle is used to puncture the sac in an area away from the fetus. The needle is inserted through the maternal abdominal and uterine walls into the pocket of amniotic fluid within the amniotic sac. A total of 10–20 ml of fluid is aspirated. The fetal cells in the amniotic fluid and the fluid itself can be assessed for various infections, birth defects, or chromosomal abnormalities. The fetal cells can be further cultured and analyzed for a more detailed karyotyping (Alfirevic et al. 2003).

Prenatal exposure to elevated cortisol, heavy metals are known to impair cognitive abilities (Bergman et al. 2007) and have long-term effects on neurodevelopment and behavior, outcomes also include symptoms of Attention Deficit Hyperactivity Disorder (ADHD) and increased distress/anxiety (Bergman et al. 2010). The exposure of these can be assessed by analyzing the amniotic fluid collected during amniocentesis.

Advancement in technology allows for the use of certain molecular markers to assess the well-being of the fetus without having to opt for invasive techniques like amniocentesis. Comparative genomic hybridization (CGH) testing, next-generation sequencing (NGS)-based noninvasive prenatal test (NIPT), noninvasive biochemical tests like dual marker test, quadruple marker test are some of the tests that are suggested to be safer options than AFT.

## Amodal Completion

Tomokazu Ushitani  
Chiba University, Chiba, Japan

## Synonyms

[Perceptual completion](#); [Visual completion](#); [Visual interpolation](#)

## Definition

A perceptual phenomenon in which the observer recognizes portions of an object occluded by another object.

## Introduction

In the three-dimensional world, objects that are farther from the observer are often partly occluded by other objects that are closer to the observer.

**Amodal Completion,**

**Fig. 1** (a) An example of amodal completion containing a T-junction. (b) A case of no completion with a figure similar to (a)

Although the occluded portions of the farther objects cast no optical information on the observer's retina, they are recognized as if the occluded portions are completed, a phenomenon called amodal completion (Michotte et al. 1991). In Fig. 1a, the observer may perceive an intact disk "behind" a square by completing the portion "hidden" by the square, although the retinal image is merely a Pac-Man-like shape (three-quarters of a circle) placed adjacent to the square, with no gap between them. (If there is a gap between them, the Pac-Man-like shape will be perceived as it is, as in Fig. 1b.)

Some have proposed that completion of occluded portions of objects occurs at a high level of cognition, such as knowledge or belief. However, there are three lines of evidence that completion occurs in a more bottom-up fashion, or at an earlier level of our visual system: 1) Kellman and Spelke (1983) reported that 4-month-old infants perceptually complete occluded portions of objects. 2) When adult participants were required to find a truncated disk, search performance deteriorated when a square was placed adjacent to the truncated disk, suggesting that perceptual completion is an inevitable, automatic process that is difficult to submit to conscious control (Rauschenberger and Yantis 2001). 3) Electrophysiological studies have revealed that neurons in primary visual cortex (V1) in macaques respond to an occluded portion of an object (Sugita 1999). Similarly, a recent fMRI study has suggested that human V1 and V2 may

code occluded portions of an object (Ban et al. 2013).

### Cues to Perceive Amodal Completion

One difference between Fig. 1a, b may be critical for amodal completion. In Fig. 1a, the contour of the disk meets the contour of the square, resulting in the formation of two T-junctions of contours, which our visual system may use to detect occlusion. When we look at Fig. 2a, an oval seems to be placed "behind" a rectangle; the center portion of the former appears to be occluded by the latter, suggesting that we perceptually complete the missing center part of the oval. Dotted circles in Fig. 2b show the four T-junctions. Kellman and Shipley (1991) have suggested that the relatability of contours is also important in completing occluded portions of figures, such that the hypothetical extension of a visible edge needs to be smoothly connected to the edge on the other side, as indicated by dotted arrows in Fig. 2b. Lack of contour relatability makes the two visible portions of the oval appear to be disconnected from each other, as in Fig. 2c.

According to Shipley and Kellman (1992), relatability is a common mechanism of amodal and modal completion. A famous example of modal completion is the well-known phenomenon of subjective contour, exemplified by the Kanizsa triangle (Fig. 3), in which we perceive a triangle

### Amodal Completion,

**Fig. 2** (a) Another example of amodal completion. (b) T-junctions and relatability. (c) Another case of no completion with a figure similar to (a)

**Amodal Completion, Fig. 3** An example of modal completion (Kanizsa illusion)

with visual attributes such as clear contours and a brighter surface “in front of” the white background. By contrast, in amodal completion, the occluded portion and contour of the occluded object can be recognized, but with no such visual attributes.

Although the mechanisms of amodal and modal completion are probably similar, modal and amodal percepts are unlikely to arise from identical processes. Determinants of the percept of an occluded portion include regularity of the overall figure (e.g., Sekuler 1994), as well as purely bottom-up cues such as T-junctions and relatability. For example, the figure of Fig. 4a may be perceived as the partly occluded hexagram in Fig. 4b, although an account solely based on relatability would predict that the completed figure must be like Fig. 4c.

**Amodal Completion, Fig. 4** (a) Another example of amodal completion. (b) Possible occluded figure in (a). (c) Possible occluded figure predicted by relatability account only

### Amodal Completion in Nonhuman Animals

Along with many other human visual functions, amodal completion may be shared with other species in the animal kingdom. A simple, non-verbal method can be used to investigate whether non-human animals do indeed experience amodal completion. As illustrated in Fig. 5, Sekuler et al. (1996) trained pigeons to select one choice stimulus when they were exposed to an intact disk and the other choice stimulus when they were exposed to a truncated disk. On each probe trial in the succeeding test phase, the pigeons were

**Amodal Completion, Fig. 5** An illustration of the procedure used by Sekuler et al. (1996)

exposed to either A) an intact disk placed “on top of” a rectangle, B) a truncated disk placed “on top of” the rectangle, or C) a stimulus in which the rectangle was placed adjacent to the truncated portion of the disk. A choice of the stimulus corresponding to the intact disk on the probe trial in which the stimulus C was presented would have indicated that the animal experienced amodal completion, but the pigeons of Sekuler et al. made the other choice, indicating that they did not experience this completion.

Other procedures are also available to investigate amodal completion in nonhuman animals: yes/no or (symbolic) matching-to-sample, go/no-go (e.g., Cerella 1980), identical matching-to-sample (e.g., Ushitani et al. 2001), and visual search (e.g., Fujita and Ushitani 2005). Cerella (1980) trained pigeons to respond to a triangle and not to respond to other figures, such as circles or stars. After the accomplishment of the training, the pigeons were tested whether they would respond to partly occluded triangles. Pigeons did not frequently respond to partly occluded triangles, suggesting that they do not experience amodal completion. In an identity matching-to-sample task (See Fig. 6), Ushitani et al. (2001) trained pigeons to match a unitary bar and a similar but broken bar (i.e., there was a gap in the

middle of the bar) to each identical bar. In the test phase, when a bar with its middle portion being occluded by a rectangle was presented as sample, the pigeons selected the broken bar, suggesting that they did not complete the occluded portion of the bar.

Fujita and Ushitani (2005) instructed humans and trained pigeons to search for a partly truncated square among intact squares. In the test phase, the target (truncated square) was placed adjacent to another square with the truncated portion of the former being filled with the latter resulting in the formation of apparently-intact square as similarly to Fig. 1a. The reaction time and accuracy for humans to find the test target deteriorated due to the completion of the truncated portion of the target, whereas those for pigeons did not, suggesting that they did not experience amodal completion.

An animal’s natural responses can also be applied: Shimizu (1998) and Takahasi and Okanoya (2013) used courtship behavior in pigeons and Bengalese finches, respectively. Whereas pigeons showed courtship behaviors to movies of a conspecific, they stopped the behaviors to the same, but partly occluded movie, suggesting that they did not complete the occluded portions of the conspecific. In contrast,

A

**Amodal Completion, Fig. 6** An illustration of the procedure used by Ushitani et al. (2001)

Bengalese fitches kept singing a courtship song to movies of a conspecific even when the movies were partly occluded, suggesting that they experience amodal completion. Lea et al. (1996) and Regolin and Vallortigara (1995) employed filial imprinting in domestic chickens. For example, Lea et al. presented newly hatched chicks with either a unitary bar, a broken bar, or a bar with its center occluded by a rectangle. Chicks imprinted on the unitary bar and the broken bar tended to approach each matching bar rather than the other. Chicks imprinted on the partly occluded bar preferred the unitary bar, suggesting that the chicks completed the occluded portion of the bar. The study by Regolin and Vallortigara resulted in the same conclusion.

Ushitani et al. (2010) demonstrated amodal completion in chimpanzees by taking advantages of object-based nature of their visual attention (Fig. 7). Ushitani et al. first demonstrated that chimpanzees' response latency to a target was shorter when the target appeared in the same rectangle in which a pre-cue had appeared than when it appeared in the other rectangle. Their response latency was also short when the pre-cue and the target separately appeared in two fragments but the fragments formed a unitary rectangle by amodal completion (Completion trial in Fig. 7). In contrast, response latency increased on the trials in which the two fragments formed no unitary figure (Fragment trial in Fig. 7). Note that no

discrimination was not required in this experiment; the chimpanzees just responded to the target.

Electrophysiology also provides us with a powerful method to investigate amodal completion in nonhuman animals. For example, Sugita (1999) recorded activities of orientation-selective cells of V1 in Japanese macaques that activated when a unitary bar was moving but not when a broken bar (i.e., a bar having a gap in the middle) was moving. The cells also activated when the gap of the broken bar was occluded by a patch, suggesting that they responded to a perceptually-unitary bar, i.e., the bar with its gap perceptually completed.

With the efforts of many research teams using the methods described above, various nonhuman animal species have been revealed to perceptually complete occluded portions of objects as humans do. Amodal completion has been demonstrated in a number of nonhuman primates, including chimpanzees (Sato et al. 1997; Ushitani et al. 2010), rhesus macaques (Fujita 2001), Japanese macaques (Sugita 1999), baboons (Deruelle et al. 2000; Fagot et al. 2006), and tufted capuchin monkeys (Fujita and Giersch 2005). Only one study has investigated whether a non-primate mammal species, the mouse, perceptually completes occluded portions of figures (Kanizsa et al. 1993). Although the choice pattern of the mice suggested that they did indeed complete the

**Amodal Completion, Fig. 7** A schematic illustration of the procedure used by Ushitani et al. (2010). Chimpanzee's response latency was short both on Same-object trial and on Completion trial whereas it was longer on Fragment trial

occluded portions, the results could also be interpreted as demonstrating a mere preference for a specific stimulus. A tentative conclusion of these studies is that amodal completion may be widely shared at least among primate species.

Results from studies of avian species have been mixed. Some research has suggested that amodal completion of occluded portions of objects does not occur in pigeons (Aust and Huber 2006; Cerella 1980; Fujita 2001; Fujita and Ushitani 2005; Sekuler et al. 1996; Shimizu 1998; Ushitani and Fujita 2005; Ushitani et al. 2001; Watanabe and Furuya 1997) and chickens (Nakamura et al. 2010, 2011). Other studies, however, have shown that special training or stimuli have enhanced amodal completion in these species (pigeons: Nagasaka et al. 2007; chickens: Forkman 1998). Because amodal completion of occluded portions requires 100–250 ms to be achieved (Rauschenberger and Yantis 2001), it appears to place a relatively heavy load on visual information processing. In terms of the ubiquitous trade-off between speed and accuracy in animal species, amodal completion may not be a default function, one that is automatic and always works,

but rather one that requires certain conditions to be triggered.

Recently, the study of amodal completion has extended to atypical species for psychological experiments. Among avian species, African grey parrots (Pepperberg and Nakayama 2016) and Bengalese finches (Takahasi and Okanoya 2013) have been revealed to complete occluded portions of figures. Studies of fish species has contributed to the literature on amodal completion, revealing that they perceptually complete occluded portions of visual objects (Darmaillacq et al. 2011; Sovrano and Bisazza 2008).

## Conclusion

Examination of more animal species would elucidate the evolution of amodal completion – when and why this cognitive function evolved. Furthermore, as shown in apparently inconsistent findings within the avian class that I have reviewed above, the investigation of species differences in the conditions under which amodal completion operates, rather than merely its existence or non-existence,

would provide additional insight on its mechanisms. More comparison between species and conditions would promisingly contribute to further understanding of amodal completion itself.

## Amygdala

Eric J. Leonardis  
Department of Cognitive Science, University of California, San Diego, La Jolla, CA, USA

### Definition

The amygdala is a historically grouped complex of 13 nuclei in the brain, together receiving inputs from and projecting to nearly every part of the

central nervous system, supporting a wide variety of functions including associative learning, emotional learning, and responsivity, as well as ingestive, sexual, and social behavior.

### Introduction

The amygdala is a historically grouped complex of 13 nuclei in the brain, each differing in structure, connectivity, and function and together receiving inputs from and projecting to nearly every part of the central nervous system (Swanson and Petrovich 1998). Amygdala circuits support a wide variety of functions including associative learning, emotional learning, and responsivity, as well as ingestive, sexual, and social behavior (Aggleton 2000). Traditionally the amygdala has been divided into the basolateral (BLA), medial (MeA), central (CeA), and cortical (CoA) nuclei, and this will be the vastly oversimplified scheme used for the purposes of this entry (Fig. 1) (McDonald 1998). Amygdalar nuclei might potentially be grouped as structural extensions of the neocortex, claustrum, and striatum but can also be functionally separated into

**Amygdala, Fig. 1** A simplified representation of the basolateral (BLA), medial (MeA), central (CeA), and cortical (CoA) nuclei of the amygdala

four systems: main olfactory, accessory olfactory, autonomic, and frontotemporal cortical systems. While some argue that the historical category of “amygdala” ought to be eliminated, there are also advocates of the term “extended amygdala,” which states that central and medial amygdala form continuous structures with the lateral and medial divisions of the bed nucleus of the stria terminalis, and thus those regions should be included as members in the amygdaloid complex (Swanson and Petrovich 1998). Cats, rats, and monkeys each have cortical connectivity with the amygdala that relay visual, auditory, and somatosensory information. More direct connectivity from olfactory, gustatory, and visceral areas is also preserved across these species bypassing much of higher-level cortical processing (McDonald 1998).

Historically, the amygdala has been mischaracterized as the “fear center of the brain”; however, the fear response is only a subset of negative affective states resulting in withdrawal, escape, and avoidance responses that involve amygdalar function (LeDoux 2003; Paré and Quirk 2017). The amygdala is not limited to negative emotional states, as amygdalar nuclei also play an important role in positive emotional states resulting in attraction or approach response, and is thus better characterized as playing an important functional role in emotional learning more generally (Gallagher and Chiba 1996). In addition to emotional and associative learning, the amygdala plays a key role in the acquisition and consolidation of emotional memories by interacting with hormonal and neuromodulatory systems (McGaugh 2004).

## Historical Developments

In 1819, Burdach first described the collection of gray matter in the anterior portion of the medial temporal lobe, which appeared to form the shape of an almond, that he coined the “amygdala” (from the Greek for “almond,” Latin for “two tonsils”). In 1867, Meynert provided an anatomical description of the structure. By 1923, Johnston provided a rich anatomical description of the

“amygdaloid complex” which he dissociated into a set of phylogenetically older set of nuclei (the central, medial, and cortical nuclei) and a newer set of nuclei (the basal and lateral nuclei) associated with olfaction (Swanson and Petrovich 1998).

In 1888, Brown and Schafer were the first to describe a taming effect on monkeys after the removal of their temporal lobes. However, the amygdala was thought to be primarily associated with olfaction until Kluver and Bucy studied the effect of temporal lobe lesions in monkeys in 1939, where they observed a wide variety of changes in tameness, hyper- and hypo-emotionality, and hypersexuality that became known as Kluver-Bucy syndrome (Gallagher and Chiba 1996). In the late 1940s, MacClean developed a theory of the “visceral brain,” which included the amygdaloid complex as a more primitive and emotional “limbic system” (LeDoux 2003). In 1952, evidence was found that temporal lobe seizures were initiated with a primary neurological discharge originating from the amygdaloid region. Building on Hess’s discovery that stimulation of the hypothalamus could elicit a range of autonomic and stereotyped behavioral responses, along with similar studies of the brainstem, a series of stimulation experiments in cats, dogs, and primates strengthened the amygdala’s hypothesized role in generating these responses (Gloor 1955). By creating more targeted lesions of the amygdaloid complex, Weizkrantz demonstrated its role in emotional learning by giving neutral cues biological significance and by showing that amygdalar damage alone could account for the symptoms observed in Kluver-Bucy syndrome (Gallagher and Chiba 1996).

From the 1960s onward, the neuroscientific study of the amygdala progressively developed “tunnel vision,” driven by NIH funding treatment of anxiety disorders. Given the region’s robust responsivity to fearful stimuli, the neuroscientific community published a vast number of papers associating the amygdala specifically with fear (Paré and Quirk 2017). The first study highlighting the role of the amygdaloid complex in classical fear conditioning was published in 1963. In 1972, it was demonstrated that amygdalar lesions

led rats to exhibit reduced freezing responses to exposure to a natural predator (cat) and to a conditioned stimulus (CS) after being paired with a shock, suggesting a key role in defensive responsiveness (Aggleton in Aggleton 1992). Subsequent key contributions detailing the functional role of the amygdala in fear conditioning cemented fear research as the most dominant paradigm in amygdala research (LeDoux in Aggleton 1992; Davis in Aggleton 1992).

### **Functional Properties of Amygdalar Nuclei (BLA, CeA, MeA, CoA)**

The basolateral amygdala (BLA), often thought of as the sensory interface of the amygdala, receives primarily excitatory thalamic and cortical sensory projections and consists of the lateral (LA), basal, and accessory basal nuclei (LeDoux 2003; Paré and Quirk 2017). Lesions to the basolateral amygdala lead to impaired conditioning where a stimulus acquires biological value and results in impaired second-order Pavlovian conditioning. Lesions to the BLA also eliminate the unconditioned stimulus (US) devaluation effect. US devaluation occurs after training a CS-US pairing, and subsequently pairing that US with a different aversive CS, resulting in a diminished CR (Gallagher in Aggleton 1992). Connectivity between the BLA and prefrontal regions allows for top-down control (Paré and Quirk 2017). The BLA is also recruited for the consolidation of emotional memory, by mediating the memory-modulating effects of stress hormones (corticosterones and glucocorticoids such as cortisol) and affecting multiple neuromodulatory systems (norepinephrine, cholinergic) (McGaugh 2004).

The central amygdala (CeA) is often thought of as the amygdalar nucleus responsible for generating behavioral and autonomic responsivity in relation to the sensory stimuli relayed from the BLA and is the main output nucleus of the amygdala with projections to brainstem, hypothalamic, thalamic, and cortical regions (Pitkanen in Aggleton 1992). The central nucleus has the capability of triggering a wide variety of autonomic responses such as tachycardia, bradycardia, hypoalgesia, endocrine arousal, respiratory changes, and the

release of insulin. Lesions to the CeA result in deficits in appetitive conditioning. CeA damage also impairs conditioned bradycardia and abolishes the fear enhancement of the startle response (Gallagher in Aggleton 1992).

The medial amygdala (MeA), functionally associated with the accessory olfactory system which emphasizes inputs from the vomeronasal organ, plays a role in pheromone and odor processing, social recognition, predator identification, and sexual behavior. The MeA receives inputs from the accessory olfactory bulb and has projections to hypothalamic regions associated with defensive and reproductive behavior (Pitkanen in Aggleton 1992; Swanson and Petrovich 1998).

The cortical amygdala (CoA) is part of the main olfactory system and receives spatially distinct inputs from the glomeruli of olfactory bulb, which are responsible for representing specific types of odorants. The innate aversion and attraction to certain odors depend on the connections between the olfactory bulb and cortical amygdala, and these responses often reflect the evolutionary history of that species. For instance, if a rat is presented with odors prevalent in predator feces or urine, such as 2,5-dihydro-2,4,5-trimethylthiazoline (TMT), the cortical amygdala will trigger innate behavioral responses such as freezing or escape behaviors despite never having actually encountered the predator within its lifetime (Rosen et al. 2015).

### **Two Examples of Emotional Processing: Auditory and Context Fear Conditioning**

In classical fear conditioning, a neutral cue or sensory stimulus (CS) is paired with a noxious US until the CS elicits a fear response. Fear is generally expressed as freezing and startle responses coupled with autonomic changes in heart rate and respiration (Davis in Aggleton 1992). In the canonical fear circuit, during auditory fear conditioning, a tone CS enters the LA via the medial geniculate nucleus of the thalamus and cortical auditory projections (LeDoux 2003; Davis in Aggleton 1992). As the CS becomes associated with the US, a dorsal group of LA

cells induce plasticity (Chapman and Chattarji in Aggleton 1992). These neurons project to the CeA which generates the autonomic and defensive behaviors via the hypothalamus (sympathetic nervous system), periaqueductal gray (freezing), and neuromodulatory systems associated with arousal (LeDoux 2003).

It is now generally accepted that the canonical fear circuit is more complex than previously envisioned. It has been shown that amygdala-projecting auditory thalamic and cortical neurons also demonstrate CS responsiveness, suggesting that the LA is not the only site of plasticity in the canonical fear circuit (Paré and Quirk 2017). LA projections to CeA are hypothesized to be mediated by feedforward inhibition from the GABAergic cells in the intercalated cell mass. Lesion studies suggest that the intercalated cells are necessary for fear extinction; they are primarily GABAergic and are hypothesized to manage the inhibitory tone of the amygdala. The intercalated cell mass also receives inputs from medial frontal cortex which play an important role in maintaining the extinction of fear (Paré et al. 2004).

When fear conditioning takes place in a particular place or context, then the fear response can generalize to that context. Contextual information is relayed from hippocampal regions to the BLA (LeDoux 2003). The medial prefrontal cortex is also posited to play a role in the representation of emotion-sensitive contextual information for context fear. Stimulation of the hippocampal neurons which project to the BLA elicits an evoked field potential in BLA, and damage to this circuitry impairs freezing to the conditioned context (LeDoux 2003). Interestingly, if an animal is allowed to avoid the place where conditioning occurred or learns how to escape from the conditioned stimulus, then BLA lesioned rats indicate the retention of fear memory (McGaugh 2004).

## Future Directions

Future directions in the field include understanding how particular cell groups in specific subnuclei of the amygdala work with the hippocampus and the prefrontal cortex to regulate

the hypothalamic-pituitary-adrenocortical axis, which have consequences for a wide variety of hormonal and neuromodulatory systems related to system-wide arousal responses (McGaugh 2004). Fear researchers are seeking to generalize their findings to more ecologically and ethologically valid experimental paradigms than traditional Pavlovian conditioning paradigms. The frontier of amygdala research involves using advanced techniques (such as optogenetic activation, precise neural recordings, and viral tracing methods) to contextualize the function of each amygdalar nuclei and their cell types within the complex networks of neural systems in which they are embedded.

## Anaclitic Depression

Sarah E. Maylott  
University of Miami, Coral Gables, FL, USA

### Synonyms

[Abandonment](#); [Depressive disorder](#); [Hospitalism](#); [Infant depression](#)

### Definition

The physical, social–emotional, and intellectual impairment of an infant’s development due to the separation from its mother or primary caregiver.

### Introduction

Anaclitic depression is a term used to describe the transient depressed state of infants after their separation from a mothering figure. This term has been used in research with human infants and animal infants, ranging from experiments with nonhuman primates to studies with guinea pigs and rats. Symptoms are similar but can vary slightly by species and by the individual mother–infant relationships pre-separation. While most studies agree that the effects of anaclitic depression are short-lived, disappearing after the

mother–infant reunion, few studies have examined potential long-term behavioral effects.

## Origins of Anaclitic Depression

Anaclitic depression was first described in a 1945 journal article titled “*Hospitalism*” by René Spitz. Spitz was a psychiatrist whose research was greatly influenced by the work of Sigmund Freud. Spitz studied child development within a psychoanalytic framework and investigated emotional deprivation in children (Blum 2011). In Spitz’s (1945) article on hospitalism, he coined the term “anaclitic depression” to convey the temporary depressed state of institutionalized infants (e.g., orphaned infants, infants removed from unfit mothers) who had been separated from their mothers for a limited period (typically less than 3 months). Spitz created this term in the context of a more extreme condition, “hospitalism” – the detrimental effects of confinement in a hospital environment – to refer to the deterioration of infants due to prolonged institutionalization. These syndromes were investigated as a result of the alarmingly high mortality rates in institutionalized infants before 1 year of age (Spitz 1945).

## Symptoms and Treatments in Human Infants

Anaclitic depression is most often associated with brief periods of emotional deprivation that occur during the first year of life, typically anywhere from 6 to 11 months of age. It appears to be triggered by the separation of the mother and infant, or as Spitz describes, the loss of a love object. Four to six weeks after the separation, the infant may begin showing striking changes in affect. Some of these symptoms can include apprehension, sadness, rejection of the environment (e.g., loss of interest in toys, people), decreased development, reduced reaction to stimuli, genital self-stimulation, slow movements, dejection, and refusal to eat. As the depression progresses the symptoms become more severe and include weepiness, withdrawal, stupor, loss

of appetite, and insomnia. Anaclitic depression appears to occur regardless of race, sex, developmental age, or intelligence (Spitz and Wolf 1946).

If deprivation last less than 3 months, then symptoms of depression may not progress to the severity of hospitalism. Spitz and Wolf (1946) offer three treatments for anaclitic depression: Prophylaxis – avoidance of infant separation from the love object (e.g., preventing mother–infant separation), restitution – restoration of the love object in the event it was deprived (e.g., returning the infant to the mother), or substitution – replacement of the love object (e.g., providing another caregiver to take the place of the mother – adoption).

### Anaclitic Depression in Nonhuman Primates

Although anaclitic depression was conventionally used to describe depression during the temporary institutionalization of human infants, it has since been generalized to other animal populations. Due to the unethical nature of experimentally inducing a state of anaclitic depression in human infants, animal models are necessary for studying this syndrome. Some of the first studies dealing with anaclitic depression in nonhuman primates took place at the University of Wisconsin Primate Laboratory in the early 1960s. During the next few decades, researchers separated mothers and infants for durations ranging from 5 min to 4 weeks to study the effects of anaclitic depression. Several of these studies also manipulated the social group that the infant was left in after separation. For example, while many of these studies kept the separated infants together in a group, one design took two infants away from their mothers and gave them each to the other mother (Jensen and Tolman 1962). In many of these cases, researchers found that the symptoms of separation paralleled those of Spitz's findings in the institutions.

A study by Seay and Harlow (1965) demonstrated the effects of separating infant rhesus monkeys (*Macaca mulatta*) from their mothers at about 7 months of age (about 30-weeks-old) for

a 3-week period. During the separation infants reacted immediately, violently protesting by screeching, running, climbing, and crying; however, soon after there was a marked decrease in infants' play activity and locomotion (Seay and Harlow 1965). In a similar study with infant pigtail monkeys (*Macaca nemestrina*), Kaufman and Rosenblum (1967) removed the pigtail mothers from their infants at an average of 6-months-old (about 26-weeks-old) for a 4-week period, leaving the infants within their original social group. The researchers found that infant pigtails reacted similarly to the rhesus monkeys, with screams of protest and struggles to reach the mother, shortly followed by agitation, pacing, searching, and lack of sleep. These symptoms lasted throughout the first day, while the following stage (24–36 h later) resulted in lethargy, genital self-stimulation, dejection, sadness, withdrawal from the environment, and slow or absent locomotion (Kaufman and Rosenblum 1967).

### Differences in Symptoms and Severity

There are notable individual differences in the severity of anaclitic depression after separation in both human and nonhuman primates. The severity of symptoms appears to be influenced by the mother–infant relationship pre-separation. For example, pigtail monkeys with more intense and insecure mother–infant relationships (infants spent less time exploring and more time in contact with their mothers, pre-separation), were associated with greater depressive symptoms in the infants; however, mother–infant relationships that were secure (infants showed more exploration and locomotion, pre-separation) were associated with little to no indicators of depression. Furthermore, pre-separation attachment is strongly associated with the mother's dominance rank within the social group. The more dominant females' infants were more securely attached, and the more submissive females' infants were less securely attached. Consequently, infants' severity of depression was negatively associated with the mothers' dominance rank; the most dominant female's infant never reached levels of

depression, while the more submissive females' infants displayed greater depressive behaviors (Kaufman and Rosenblum 1967).

Conversely, Spitz and Wolfe (1946) postulate the opposite effect in human infants. Based on his findings, he suggests that it is more difficult to replace a love object in which the infant is strongly attached. Although, his definition of attachment is unclear, denoted with categories of "good" and "bad" and ranging from "weak" to "intense," suggesting that the severity of symptoms is influenced most by the intensity of the relationship (e.g., more intense relationships associated with more depressive symptoms). Like human infants, monkey infants showed a decrease in their social interactions; however, unlike human infants, monkey infants' social contact began to recover as the separation period progressed, and almost reached pre-separation levels in the fourth and final week of the separation period. Infant monkeys also never lost interest in food, and were never considered ill, although, the pigtail infants had a sickly appearance (Kaufman and Rosenblum 1967).

These species' differences may be explained by the greater probability of survival of monkey infants without their mother compared to human infants without their mother. Monkey infants have greater locomotion abilities at this stage, and, therefore, can be more proactive in their social environment than human infants. Monkey infants can seek out a new source of comfort, increasing their likelihood of survival, while human infants are still dependent on older members of their social group, even as their locomotion ability increases (e.g., assistance walking, climbing stairs) (Kaufman and Rosenblum 1967).

Much like Spitz observed in human infants, Seay and Harlow (1965) observed that the separation appeared to have only a transient effect on the mother–infant relationship, giving further evidence that anaclitic depression is a temporary state. Kaufman and Rosenblum (1967) supplement this idea, concluding that the separation, at least in the short-term, created a closer relationship between mother and infant. These studies, however, are inconclusive regarding the long-term effects of anaclitic depression caused by the

brief separation of mothers and infants in both human and nonhuman primate infants.

To date, there are few studies with follow-up observations of human or animal infants (Zeanah et al. 2003). Some researchers suggest that separation during this period can have lasting effects. For example, Spencer-Booth and Hinde (1971) found that rhesus monkey infants separated from their mothers for only 6 days showed lasting effects documented up to 2 years after separation. Twelve months after separation and reunification, rhesus monkeys were observed to have more dependence on and greater proximity maintenance to their mothers, depressed locomotion, and more hesitation toward strange objects or situations than their nonseparated peers. These symptoms did decrease over time; however, they were still present 2-years post-separation (Spencer-Booth and Hinde 1971).

## Anaclitic Depression in Other Animals

While humans and nonhuman primates make up the majority of subjects in studies on anaclitic depression, this syndrome has been shown in other species. Albino Hartley guinea pigs (*Cavia porcellus*) who were separated from their mother for a short period, displayed increased vocalizations and crouched, lethargic states (Hennessy et al. 2017). Another study looked at these depressive behaviors in Wistar rat pups to examine separation behaviors in a species more distantly related to humans. The researchers found that rat pups showed greater activity and were less likely to sleep than their nonseparated peers. These behaviors were similar to the increased agitation and vocalizations observed in monkey infants (Hofer 1973), showing that this syndrome occurs across a wide variety of animals.

## Conclusions

Renee Spitz coined the term anaclitic depression to help explain the temporary depressive qualities of infants in institutionalized care. Anaclitic depression has since been generalized to many

other species, including nonhuman primates, as well as guinea pigs and rats. These animal models of anaclitic depression allow researchers to manipulate mother–infant separation when human experimentation becomes unethical. Further, the aforementioned animal studies help reinforce and expand upon Spitz’s original definition of anaclitic depression, providing additional evidence for anaclitic depression interventions.

It should be noted that even though the term “anaclitic depression” was created to describe the depressive state of temporarily institutionalized infants or infants experiencing loss of a love object; it is sometimes used to refer to adults who have intense attachments to relationships.

## Anagenesis

Robert Lickliter

Department of Psychology, Florida International University, Miami, FL, USA

In the general sense, evolution can be characterized by three distinct phenomena: (1) adaptation, the remarkable fit between an organism and its environment, (2) diversity, the great variety of extinct and extant organisms, and (3) complexity, the intricacy of the organization of internal and external structure and function (Muller and Olsson 2003). *Anagenesis* refers to the idea that there are directional trends in this complexity. In particular, a hierarchy of increasing levels of organization from the simple to the complex characterizes the diversification of species. As Dobzhansky et al. (1977, p. 236) put it in their classic text *Evolution*, anagenesis creates “organisms with novel characters and abilities beyond those of their ancestors.” In evolutionary biology, anagenesis refers to the progressive evolution of a species resulting in linear descent (phyletic

divergence); in contrast, cladogenesis refers to speciation by evolutionary splitting of a lineage (branching) to additional species.

The concept of anagenesis has also been used in comparative anatomy, comparative physiology, comparative endocrinology, as well as comparative psychology (Rensch 1959). Rensch identified several defining features of anagenesis, including: (1) increased complexity (differentiation), (2) centralization of structures and functions, (3) special complexity and centralization of the nervous system, (4) increased plasticity of structures and functions, and (5) increased independence from the environment and increasing command of environmental factors (progression of autonomy). Of course, independence from the environment is a relative concept, as no organism is ever free from its environment. When applied to the comparative study of behavior, anagenesis has typically referred to the progressive evolution of adaptive behavior, learning ability, or cognitive capacity that is often accompanied by the emergence of new psychological capacities (Gottlieb 1984).

The steps or units of anagenesis are typically referred to as “grades” or, in some cases, “levels” (Aronson 1984). A grade or level can be seen as an ascending series of improvements or increases in complexity of any structural or functional unit of analysis within animal groups that may or may not be closely related from a phylogenetic standpoint (Gottlieb 1984). Grades or levels thus address the ranking of behavioral organization (i.e., ability to exhibit various forms of learning, levels of exploratory behavior) relatively independent of strict evolutionary lineages (phylogenetic relationships). As a result, anagenetic analysis has been used most successfully to characterize grades or levels of behavioral complexity at the supraspecific level, that is, across genera, families, orders, or classes, rather than at the level of species. Examples include patterns of organization of the nervous system, increases in developmental plasticity, and improvements in behavioral versatility or adaptability to environmental change (Yarczower 1998). For example, within the order Chiroptera (bats), researchers have demonstrated that the relatively large brain observed in some bat species is associated with adaptations used

to feed on energy-rich foods that are often unpredictable in their spatial distribution (Eisenberg and Wilson 1978). Such descriptions of the specific fit between phenotypes and environments across genera provide a foundation for further studies of both adaptation and diversity.

Schneirla (1949) was among the first comparative psychologists to promote the importance of levels of psychological capacities to frame the comparative study of animal behavior. His anagenetic concept of levels (see Greenberg, this volume) emphasized the value of recognizing and assessing the range of differences in complexity, degree of development, and organization of behavior functions across different types of animal species. This type of approach has been termed “pheneticism” within evolutionary biology (Harvey and Pagel 1991), where grade or level is determined by similarity in phenotypic characters or traits rather than by phylogenetic relationships (common ancestry). For example, Tobach and Schneirla (1968) proposed a hierarchy of behavioral levels based on social and psychological organization: taxis, biotaxis, biosocial, psychotaxis, and psychosocial (see Greenberg, *Behavioral Levels*, this volume). Using this hierarchy, Greenberg (1995) noted that in the general sense, animals demonstrate less behavioral plasticity or versatility function at lower behavioral levels (i.e., taxis, biotaxis), whereas they demonstrate more behavioral plasticity or versatility function at higher behavioral levels at which psychological processes influence the course of behavioral development (i.e., psychotaxis, psychosocial). Importantly, increased behavioral plasticity is highly correlated with increasing nervous system size, complexity, and organization (Jerison 1973; Jerison and Barlow 1985). Gottlieb (1984) extended this approach to anagenesis by emphasizing that developmental plasticity and behavioral versatility are useful hallmarks of progressive behavioral evolution. He argued that application of this perspective allows a measure of anagenesis to be obtained by comparing different animals’ behavioral adaptability in response to experimentally altered ecological conditions or challenges. However, this ecologically based approach to testing anagenesis has received little research attention to date.

The concept of anagenesis and its use of grades or levels to compare behavioral evolution across animal species independent of strict evolutionary lineages have not been without criticism within comparative psychology (i.e., Capitanio and Leger 1979; Hodos and Campbell 1969, 1990). It is certainly the case that objective criteria for how to best distinguish successive grades or levels of developmental plasticity and behavioral versatility remain poorly defined. Hodos and Campbell (1969, 1990) see comparing evolutionary trends across groups of animals that are not closely related by way of common ancestry as overly subjective and even unscientific. They argue that most comparative psychologists do not base their work on strict evolutionary lineages (i.e., phylogenetic trees), which they view as the appropriate subject matter of a genuine comparative psychology. While such criticisms have been challenged (e.g., Gottlieb 1984; Greenberg 1995), it is clear that an objective description of the criteria used to identify differences in behavioral plasticity or versatility between higher and lower grades of animal species is crucial to the merit and usefulness of anagenetic analysis. Given that the comparative method has been the most general and effective technique for asking questions about the patterns of evolutionary change from Darwin to the present, comparisons of animal behavior and cognition using *both* evolutionary trends and evolutionary lineages will likely provide a deeper understanding of the phenomena of adaptation, diversity, and complexity.

## Analogical Reasoning

Joël Fagot

Aix-marseille University, CNRS, and Brain and Language Research Institute, Marseille, France

## Synonyms

Relational matching; Relational thinking

## Definition

A process of reasoning based on a similitude of relations which is perceived between the objects compared.

## Introduction

Reasoning by analogy is one of the most complex forms of abstract thinking in humans. Consider the following analogy: the fish is to water what the bird is to air. To understand this analogy, one must first determine the relation between a first set of stimuli (i.e., the fish is *in* the water) and subsequently search for that same functional relation between the second set of stimuli (e.g., the bird is *in* the air). In other words, this two-step process therefore requires that we first appreciate first-order relations (the fish:water and bird:air relations), and subsequently compare and judge the relation between these relations (second-order relation). This form of inferential process based on analogical reasoning is fundamental for a diversity of cognitive processes of considerable importance in humans, such as classification, transfer of learning in new contexts, problem solving, and creative thinking. The hypothesis has been repeatedly made that our exceptional abilities for analogical reasoning would be the major contributor to our high intelligence as a species (Hofstadter 2001; Gentner 2003).

One reason for which analogical reasoning is interesting is that it appears to be linked with human language. First, children with specific language impairment express difficulties in analogical tasks (Leroy et al. 2012). Second, although children already demonstrate rudiments of analogical reasoning at 2 years of age (Singer-Freeman 2005), their performance in analogy tasks at 3–4 years of age is fostered by their emerging capacity to represent abstract relations via linguistic labeling (Christie and Gentner 2013). Moreover, analogical reasoning does not approach adult-like performance until adolescence and the full growth of linguistic competencies (Richland et al. 2006).

## Analogical Reasoning in Nonhuman Animals

Comparative studies with nonhuman animals have questioned whether language is a prerequisite for complex forms of analogical reasoning. In this chapter, we will firstly document the fact that nonhuman animals have the capacity to process first-order relations. We will then document their ability for processing second-order relations, in other words, the relations between relations.

### Processing of First-Order Relations in Nonhuman Animals

Many animal species can judge relations between things. For instance, baboons can be trained to indicate if one object is above or below another object (Dépy et al. 1999). Particularly important for analogical reasoning is the abstract concept of sameness (identity). Using a wide variety of experimental tasks, researchers have shown that many animal species, including the chimpanzee, rhesus monkey, baboon, parrot, pigeon, rat, and even honeybee and bumblebee, have sufficient cognitive power to indicate if two things are identical or different (see review in Wasserman et al. 2017). In these experiments, the identity concept is presumed to be abstract, because the subjects express accurate same/different responses even when they must judge the relation between objects never seen before.

### Processing of Second-Order Relations in Language or Symbolic Competent Apes

Gillan et al. (1981) published the first paper on second-order relational processing in animals. These authors tested an enculturated language-trained chimpanzee (*Pan troglodytes*) named Sarah, who had already learned the symbolic meaning of pieces of plastic and could use and combine these symbols as words in sentences to communicate with the experimenter. In one first test condition, Sarah saw a tray containing one pair of objects on one side, and one single object on the other side. Two other objects were shown below the tray, and Sarah had to indicate which of these two objects would complement the single object on the tray, so that the relations entertained

by these two objects is equivalent to the relations shown by the other stimulus pair. In another version of the task, Sarah was presented with two stimulus pairs, and she had to indicate if these two stimulus pairs showed the same or a different relation. She did so by selecting one piece of plastic symbolizing the same or different relations. Sarah was successful in these two versions of the task involving stimuli varying in shape, color, and marking. Moreover, she continued to be correct when the same tasks required the appreciation of functional relations between known household objects (e.g., closed lock and key vs. closed can and can opener). Considering Sarah's initial training with symbols, Premack (1983) logically considered that Sarah's success in the task of analogical reasoning can be explained by the cognitive competencies she developed via her "language" training.

The task used by Gillan et al. (1981) has never been replicated with other animal species. Later research on analogical reasoning in nonhuman animals has used instead the relational matching-to-sample task which is illustrated on the left side of Fig. 1. In this task, the subject first perceives one pair of objects that are either identical or different. Two other pairs are then presented, and the subject must select the pair exemplifying the

same (same or different) relation as the sample pair. One important feature of this task is that the items composing the sample are not used in the comparison pairs. Matching is therefore impossible of the sole basis of the individual items. Admittedly, the relational matching-to-sample task captures several features of analogical reasoning, because it requires the apprehension of the relation between pairs of items (first-order relation), and also the processing of the relation between relations (second-order relation).

Premack's (1983) conclusion that language training is required for analogical reasoning was questioned by Thompson et al. (1997). These authors tested five chimpanzees on a version of the relational matching-to-sample task using pairs of real objects or digitized images. One of the subjects was the language-trained chimpanzee Sarah cited above. Three other chimpanzees were language-naïve, but these subjects had previously learned the meaning of two different token shapes, each symbolizing the same or different relation. The last chimpanzee was both language- and symbol-naïve. Sarah and the three token-trained chimpanzees could successfully solve the relational matching-to-sample task, with no reliable difference among them. By contrast, the last chimpanzee who was both language-

**Analogical Reasoning, Fig. 1** Illustration of two different versions of the relational matching-to-sample task. In both versions, the subject must indicate which of the two comparison stimuli (i.e., the match) instantiate the same

relation as the sample stimuli. In the left-most version, the same different/relations are illustrated by pairs of stimuli. In the right-most version of the task, the same/different relations are shown by arrays of icons

and token-naïve failed miserably in the task. From their results, Thompson et al. (1997) concluded that the ability to process the relation between relations requires at least a form of symbolic/token training. This conclusion was however premature, as shown below.

### Processing of Second-Order Relations in Language-Naïve Primates and Birds

Most of the initial attempts to present the relational matching-to-sample task to language- or token-naïve animals were failures (see review in Thompson and Oden 1996, 2000). However, the picture began to change when researchers reasoned that relational matching could be facilitated if the relations are shown in arrays of multiple stimuli, rather than same/different stimulus pairs. Following this reasoning, Fagot et al. (2001) trained two Guinea baboons (*Papio papio*) in a version of the relational matching task using arrays of 16 (same or different) icons as sample and comparison stimuli. Figure 1 (right side) illustrates the kind of displays used in this task. The two baboons tested in Fagot et al. (2001) could achieve a high level of performance during the training phase. After training, they even continued to be above chance when a new set of icons was used to create each array, suggesting an ability to match relations between relations. The success of the baboons with arrays of icons prompted Cook and Wasserman (2007) to replicate that procedure with pigeons (*Columba livia*). These authors found that the birds could achieve 70% correct at the end of the training period. Much like baboons, the pigeons could also transfer their performance to new sets of stimuli. These findings were the first demonstrations that monkeys and pigeons have the capacity to match relations between relations.

A different approach to the problem was to capitalize on potential benefits of extensive training in the relational matching task. This procedural strategy was possible thanks to the most recent technological developments allowing the animals to be tested via an automated identification, with no need to remove them from their social group. Fagot and Thompson (2011) used this procedure with a group of 29 Guinea baboons (*Papio papio*) tested with a version of the

relational matching-to-sample task shown on the left of Fig. 1. Most of the baboons failed to learn the task, but five of them did. These five individuals could moreover maintain a high level of performance with stimuli never seen before. The fact that nonhuman primates can learn the relational matching-to-sample task with pairs of items is further confirmed in one capuchin (*Cebus apella*), among five, by Truppa et al. (2011). The training phase required approximately 17,000 trials in this study on capuchins, which is in the same range as for baboons (Fagot and Thompson, 2011).

In a more recent project, Smirnova et al. (2015) tested two hooded crows (*Corvus cornix*) which had already been trained on the identity concept. This study used pairs of shapes drawn on carton boards as stimuli in the relational matching-to-sample task. To obtain a bait, the crows had to lift the carton board showing the same relation as the sample board. The crows readily displayed high levels of relational responding in this task, and they did so in several versions of the task requiring an appreciation of the relations expressed by stimulus size, shape, and color. The authors explained this astonishing performance by the initial training that the birds have received on the identity concept. An earlier study on language-naïve orangutans (*Pongo pygmaeus*) and gorilla (*Gorilla gorilla*) had already shown that these animals can achieve a high level of performance in the relational matching task without extensive training (Vonk 2003).

### Are There Alternative Explanations to Relational Responding?

The possibility that nonhuman animals have sufficient cognitive capacities for second-order relational thinking remains a matter of hot debate, and researchers have examined alternative explanations that could explain their behavior in the relational matching-to-sample task. Penn et al. (2008) proposed that the nonhuman animals consider for responding the entropy of the displays in the relational matching-to-sample task, rather than the relations among the items present in the displays.

The concept of entropy has been introduced in this literature by Young and Wasserman (1997), and it corresponds to the degree of perceptual variability between the elements contained in each display. Following Penn et al.'s idea, the subjects would consider that an array containing different icons is more variable than an array containing identical items. This type of encoding would allow the matching of same or different arrays in the relational matching task on the sole basis of a global apprehension of the perceptual variability of the sample and comparison displays, rather than their relational properties. This hypothesis was directly tested by Flemming et al. (2013). Using arrays of icons containing only four items, they manipulated the entropy of the sample independently of their relation. They used sample stimuli which had the following possible structures: AAAA (all same icons, entropy = 0), AAAB (entropy = 0.81), AABB (entropy = 1.0) and AABC (entropy = 1.5), ABCD (all different icons, entropy = 2), with the location of each item randomized across trials. In a comparative perspective, these authors have also tested humans and baboons in this task. In the two species, results indicated that the relational structure of the sample arrays was the primary variable controlling subjects' choice performance. An effect of entropy was also revealed by the results, in both humans and baboons, but in both species this effect was secondary to the effect of the relations. This result is an additional confirmation that nonhuman animal species have the capacity to solve the relational matching task, and that their performance is controlled by the relational structure displays.

## Conclusions

Analogical reasoning is considered a hallmark of higher-order reasoning, and recent theoretical perspectives assert that this is a uniquely human cognitive trait (Penn et al. 2008). The close relationship found between the development of analogical reasoning and the emergence of language competence in children supports the conclusion that a linguistic mode of encoding is needed for

the emergence of complex forms of relational thinking. An initial study in a language-trained chimpanzee has supported this conclusion (Gillan et al. 1981; Premack 1983). However, more recent attempts to investigate the extent and limits of relational thinking in linguistic-naïve animals have shown that several species, including the pigeon, capuchin, baboon, chimpanzee, gorilla, and orangutan, can demonstrate second-order relational processing in the relational matching task (for an extensive review of this literature, see Wasserman et al. 2017). All these findings demonstrate that linguistic competences are not necessary for complex relational thinking, although a linguistic encoding of the task might of course help (e.g., Christie and Gentner 2013). One obvious limitation of this literature is that it probably focuses too much on the relational matching-to-sample task. Admittedly, this task cannot capture the full complexity of the processes involved in analogical thinking in humans, for instance, when we solve verbal analogies as complex as the well-known analogy which compares the solar system to the *Rutherford* atom model. The relational matching-to-sample task nevertheless contains some of the most basic features of analogical reasoning, among them the fact that the subjects must associate relation between relations. A close examination of the current comparative data suggests that nonhuman animals possess at least some of the cognitive antecedents of analogical reasoning in humans.

## Andrew Whiten

Lydia M Hopper

Lester E. Fisher Center for the Study and Conservation of Apes, Lincoln Park Zoo, Chicago, IL, USA

### Biography

Andrew (Andy) Whiten is Emeritus Wardlaw Professor at the School of Psychology and Neuroscience, University of St Andrews, Scotland. He is an elected Fellow of the British Academy, the Royal Society of Edinburgh, and the International Cognitive Science Society. Whiten's research focuses on social learning and cultural transmission, providing insights into this "second inheritance system" and the role it plays in shaping behavior in concert with genetic inheritance and individual learning. Through his collaborations, Whiten has published papers on humans and non-human primates and has used experimental and observational techniques to answer questions about the social drivers of primate cognition.

Whiten joined the University of St Andrews as a Lecturer in 1975 after studying at the Universities of Sheffield, Bristol, and Oxford. He became Professor of Evolutionary and Developmental Psychology at the University of St Andrews in 1997 and was made Wardlaw Professor in 2001. In 2003, Whiten founded the Center for Social Learning and Cognitive Evolution and 5 years later established the Living Links to Human Evolution primate research center, housed at Edinburgh Zoo, providing a forum for public engagement with science in a zoo setting.

### Behavioral Ecology of Baboons

Whiten's early research focused on the behavioral ecology of chacma baboons (*Papio ursinus*) living in the Drakensberg mountains of South Africa and, later, olive baboons (*P. anubis*) in Kenya. This field research was conducted in collaboration with Richard Byrne, Peter Henzi, and Robert Barton.

### Machiavellian Intelligence

Initially inspired by their observations of "tactical deception" in wild baboons, in their 1988 book *Machiavellian Intelligence*, Andy Whiten and Richard Byrne highlighted links between the various aspects of primate intelligence in the social domain (Byrne and Whiten 1998). Framed against the earlier work of Nicholas Humphrey and Alison Jolly, Byrne and Whiten curated a volume of both new and previously published chapters that provided support for the "social intelligence hypothesis." Thirty years on, the ideas put forward in *Machiavellian Intelligence* still resonate and continue to be investigated in contemporary studies of primate cognition and behavior.

### Chimpanzee Culture

In the 1990s, Whiten led a consortium of primatologists to publish a report on chimpanzee behavior studied at long-term field sites across Africa (Whiten et al. 1999). In this seminal article, the authors compared the behavioral repertoires of chimpanzees living in seven different communities: Bossou (Guinea), Taï Forest (Ivory Coast), Gombe (Tanzania), Mahale M-group (Tanzania), Mahale K-group (Tanzania), Kibale Forest (Uganda), and Budongo Forest (Uganda). Through this collaborative effort, the authors identified 39 behaviors that were observed to be performed by chimpanzees in certain communities but not others. The authors proposed that the variance in behavioral patterns could be "seen to resemble those in human societies, in which differences between cultures are constituted by a multiplicity of variations in technology and social customs" (Whiten et al. 1999, p. 685), an idea that they crystalized as *Cultures in Chimpanzees*. This collaborative endeavor was expanded to include two additional sites (Lopé, in Gabon, and Assirik, in Senegal), and in a follow-up paper, the authors reviewed chimpanzee behaviors that were universals and others for which an environmental cause could be attributed, in addition to possible socially learned cultural behaviors (Whiten et al. 2001). When they published their original paper, Whiten

et al. (1999) recognized that behavioral traditions might not be unique to chimpanzees and such traditions have since been reported for a variety of other primate species, including orangutans, capuchin monkeys, and spider monkeys, as well as nonprimate animal species. While *Machiavellian Intelligence* called researchers to question behavioral theories of technical intelligence and instead to consider social influences on cognitive evolution, *Cultures in Chimpanzees* (Whiten et al. 1999) called us to question the uniqueness of human culture and the potential power of social learning in shaping animal behavior.

### Experimental Methods for Studying Social Learning

To gain a deeper understanding of the social and cognitive mechanisms that underlie primate social learning, Whiten has conducted numerous experimental studies with wild and captive nonhuman primate populations and also with human participants. Much of this research has incorporated a two-action task that can be solved in one of two arbitrary ways. The use of a two-action task allows the researcher to determine both if the naïve subject can learn a solution from observing an expert and also if they use the same method as the expert to do so. To increase the ecological validity of such tests, Whiten created tasks designed to mimic the actions required by wild primates to remove the tough casings of wild fruits or to obtain foods like honey or insects via extractive foraging techniques (Whiten et al. 1996). These tasks, dubbed “artificial fruits,” have ranged in their design and complexity, allowing researchers to test the fidelity of social learning (e.g., imitation versus emulation); hierarchical and serial imitation, and the ability of primates to make and use tools to extract food from these devices.

Whiten employed one such two-action task (the “pan-pipes”) in a groundbreaking study of captive chimpanzee social learning of tool use, run in collaboration with Victoria Horner and Frans de Waal (Whiten et al. 2005). Rather than

simply testing the transmission of information between two individuals as previous social learning tests had done, Whiten et al. (2005) exposed two entire groups of chimpanzees to a trained chimpanzee model in an “open diffusion” test design. Not only did this study show that the majority of observer chimpanzees were able to learn the task from observing the trained model, but also that they predominantly matched the specific method used by the model. Thus, the newly introduced behavior spread throughout each of the two social groups tested, mimicking culturally transmitted behavioral variation reported for wild chimpanzee communities (Whiten et al. 1999). Furthermore, the findings from this study challenged previous assumptions about primate social learning (i.e., it was restricted to enculturated individuals raised in human-centric environments or that social learning could only occur during the juvenile years). This open diffusion technique has subsequently been applied to study social learning in other nonhuman primate species and with human children. It has also been adapted to ask more nuanced questions about how, what, and when information is transmitted among primates (Kendal et al. 2015).

Whiten and colleagues have also run “diffusion chain” experiments, akin to the “telephone game,” that mimic vertical transmission down generations. This method provides more experimental control over what information is transmitted, as well as who has the opportunity to learn from whom. Whiten has applied this to chimpanzees, orangutans, and human children, revealing high-fidelity transmission of behavioral foraging techniques.

### Diversity in Studies of Social Cognition in Captive Primate Populations

The majority of Whiten’s research with captive primates has focused on social cognition, with an emphasis on social learning. His work with captive primates has encompassed a broad phylogenetic perspective, with studies being run with chimpanzees (*Pan troglodytes*), gorillas (*Gorilla gorilla gorilla*), orangutans (*Pongo abelii* and

*P. pygmaeus*), capuchin monkeys (*Cebus apella*), squirrel monkeys (*Saimiri sciureus*), and marmoset monkeys (*Callithrix jacchus*). This research has been run at a variety of facilities including sanctuaries (e.g., Ngamba Island Chimpanzee Sanctuary, Uganda), zoos (e.g., Zoo Atlanta, USA, and Edinburgh Zoo, UK), and laboratories (e.g., Yerkes National Primate Research Center, USA, and UT MD Anderson Cancer Center, USA). Beyond confirming the social diffusion of behaviors (Whiten et al. 2005), Whiten's work has attempted to tease apart social learning strategies ("who" do primates copy, e.g., Kendal et al. 2015) and mechanisms ("what" do primates copy, e.g., Hopper et al. 2015), as well as the social and environmental conditions that best support social learning (Caldwell and Whiten 2003).

### Studies with Wild Primate Populations

In recent years, Whiten has expanded his experimental studies of primate social learning to include field research, returning to South Africa, but now to study vervet monkeys (*Chlorocebus aethiops*). Working in collaboration with Erica van de Waal at her field site, as part of the Inkawu Vervet Project, Whiten has been involved in a number of field experiments on social learning (e.g., van de Waal et al. 2013). Through the use of artificial fruit tasks and the provision of novel foods, van de Waal, Whiten, and colleagues have revealed when and how information is transmitted among monkeys within a troop, as well as shedding light on how monkeys weigh their own personal experience against social information when they emigrate to a new group. These field experiments either reflect or have stimulated "sister" studies run with captive primates, allowing comparison between captivity and the field, as well as across species (e.g., Vale et al. 2017).

### Studies with Human Children

From early times Whiten's experimental work investigating primate social learning was

comparative, including both human and non-human primate subjects (Whiten et al. 1996). He has continued to provide a comparative perspective throughout his career. Just as with nonhuman primates, Whiten has tested human children with artificial fruit analogs, in dyadic, diffusion chain, and even open diffusion paradigms (Whiten and Flynn 2010). His work has revealed both the similarities and differences in how we learn new skills compared to our nonhuman cousins and has expanded to include work focused on other areas of social cognition (e.g., prosociality, Claidière et al. 2015). To better understand the relationship between children's theory of mind understanding and their capacity to learn from others, Whiten has also investigated the social learning capacities of children with autism (e.g., Williams et al. 2001).

### Public Engagement with Science

In addition to conducting research, Whiten has demonstrated an extensive commitment to public engagement with science, particularly evident in the design of the Living Links to Human Evolution research center at Edinburgh Zoo, of which Whiten was a founding director. At Living Links, visitors to the zoo can observe scientists running behavioral and cognitive research within two mixed-species communities of capuchins and squirrel monkeys. The dedication Whiten has shown to public understanding of science was recognized by the Royal Society of Edinburgh, who awarded him their Senior Prize and Medal for Public Engagement in 2014.

### Legacy

Whiten's impact on the field of comparative psychology, particularly on the study of primate social cognition, is far reaching. Both through his own research and that of his collaborators and former students, Whiten's theories and research findings continue to influence the field. His legacy is recognized both through the

continued relevance of his work and also through the awards he has received throughout his career that include the Osman Hill Medal, awarded by Primate Society of Great Britain in 2010, the Sir James Black Medal, awarded by the Royal Society of Edinburgh in 2013, and from honorary degrees bestowed by Heriot Watt University (2015), the University of Stirling (2016), and the University of Edinburgh (2017).

## Androgen

- [Psychopharmacology of Sex Steroids](#)

## Androgens

Rachna Verma

Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

## Synonyms

Male hormone; Sex hormone; Testosterone

## Definition

Androgens are steroid hormones that play a determining role in the growth and perpetuation of male phenotype and reproductive functions.

## Introduction

Androgens are synthesized and secreted into blood stream abundantly in the form of testosterone (T) and regulates the reproduction, physiology, and metabolism of males. In majority of the cases, androgens are found to exert their effects by genomic pathways, which involve binding of androgens to the androgen receptor (AR) present in the nucleus; ultimately, this hormone receptor combo binds to the specific portions of DNA and bring out the response (Kang et al. 2003). In some cases, AR-induced nongenomic mechanisms have also been reported. Adequate amount of androgens is very necessary for successful reproduction and metabolism of males, and any alterations in the amount or improper signaling result in diseased conditions like androgen insensitivity syndrome (AIS), infertility, and prostate diseases. Nowadays, a large number of steroidal and nonsteroidal AR-ligands are used in the treatment of male hypogonadism (AR agonists) and prostate diseases (AR antagonists) and among other pathological conditions.

## Androgen Biosynthesis

The human testis is a complex organ made up of two different units: androgen producing Leydig cells of the interstitial compartment and sperm producing seminiferous tubule compartment which makes around 90% of the testis volume (Melmed et al. 2011). Testosterone (T) produced in the testis plays a critical role in sex development, sexual function, and reproduction.

Androgens are produced from cholesterol (C-27) by using a cascade of enzymes which are encoded by genes that are present in all steroid producing organs (Auchus and Auchus 2012). Cholesterol is stored in esterified form as lipid droplets in steroid producing Leydig cells. Trophic hormone initiates steroidogenesis by activating a chain of reaction that lead to hydrolysis of cholesterol esters into free cholesterol. The free cholesterol formed is transported into mitochondria by intracellular cholesterol transporters such as steroidogenic acute regulatory protein (StAR), sterol carrier protein 2 (SCP<sub>2</sub>), and peripheral benzodiazepine receptor (PBR). In the mitochondria, cholesterol is converted to pregnenolone (C-21) by the side chain cleavage enzyme complex that consist of *CYP11A1* (P450<sub>scc</sub>), ferredoxin (FDX1), and ferredoxin-reductase (FDR). In the classic pathway, pregnenolone is then converted through the  $\Delta 5$  pathway by *CYP17A1*(P450<sub>c17</sub>) to 17-hydroxypregnenolone (17OHPreg) and dehydroepiandrosterone (C-19) (DHEA) with the first reaction catalyzed by its 17 $\alpha$ -hydroxylase activity supported by P450 oxidoreductase (*POR*) and the second reaction by the 17,20 lyase activity supported by *POR* and cytochrome b5 (*CYB5*). Further, DHEA is converted to testosterone through androstenedione and the reaction is catalyzed by 3 $\beta$ -hydroxysteroid dehydrogenase type II and 17 $\beta$ -hydroxysteroid dehydrogenase 3. Testosterone may be converted to DHT which has about 10 times more affinity for the androgen receptor. This conversion is catalyzed by 5 $\alpha$ -reductase type II which is expressed in genital skin and the prostate. In humans, only little conversion to androstenedione occurs through the delta 4 pathway coming from progesterone (Prog) and 17-hydroxyprogesterone

(17OHP) because 17,20 lyase activity is poor on the substrate 17OHP compared to 17OHPreg (Flück et al. 2003).

## Androgens in Females

Quantitatively women secrete greater amount of androgen than estrogen. On the basis of maximum to minimum levels of steroids found in serum of women the sequence is dehydroepiandrosterone sulfate (DHEAS), dehydroepiandrosterone (DHEA), androstenedione (A), testosterone (T), and dihydrotestosterone (ref1). The overall effects of androgens in females are lower than estrogen because among all the androgens, receptors are only present for testosterone (T) and dihydrotestosterone. Remaining three androgen steroids are called pre-androgens. These androgens are produced from different zones of adrenal (zona reticularis and zona fasciculata) and ovaries (ovarian theca and ovarian stroma). Testosterone production does not get altered with age in females, but the levels of steroid hormones binding (SHBG) get decreased which lead to increase in the level of circulating testosterone in menopausal females (Burger 2002).

## Androgen Receptor Structure

Androgen receptor (AR) is a member of nuclear receptor family. These receptors function as a ligand inducible transcription factors. AR mediates the expression of target genes after binding to the androgens.

Androgen receptors are classical type of nuclear receptors. The androgen receptor (AR) (NR3C4, nuclear receptor subfamily 3, group C, gene 4) belongs to the steroid hormone group of nuclear receptors and having similarity with the estrogen receptor (ER), glucocorticoid receptor (GR), progesterone receptor (PR), and mineralocorticoid receptor (MR) (McKenna et al. 1999; Mangelsdorf et al. 1995). Male sexual development and differentiation is started via

binding of the AR to its native ligands testosterone and 5 $\alpha$ -dihydrotestosterone (DHT).

The human AR gene is located on X chromosome at position Xq11-q12 (Lubahn et al. 1988). Like other members of its family, the structure of AR is organized into functional domains, consisting of an N-terminal domain (NTD), a DNA-binding domain (DBD), and a C-terminal ligand-binding domain (LBD) (Kuiper et al. 1989). There is also a small hinge region between DBD and LBD. Whereas the DBD and LBD of the AR are highly conserved among species, the NTD displays the most sequence variability, which is important for differences in the homeostatic control and complexity of AR signaling (Li and Al-Azzawi 2009). The AR NTD is relatively long, representing almost half of the receptor coding sequence; it contains the major transactivation function domain of the AR, termed activation function 1 (AF1), which is responsible for almost all AR transcriptional activity (Simental et al. 1991). AF1 also interacts with transcriptional coregulators and members of the basal transcriptional machinery (Kumar and Litwack 2009). Another transcriptional activation domain AF-2 is situated in LBD portion (Kang et al. 2003). The mutation and deletion of this domain dramatically reduce the transcriptional activation of AR in responses to androgens.

Androgens such as testosterone are synthesized primarily by the Leydig cells in the testes, under the regulation of luteinizing hormone (LH) produced by the anterior pituitary gland. LH secretion is in turn regulated by gonadotropin-releasing hormone (GnRH). Male sexual differentiation fails to occur in the absence of androgens or without a functioning AR. A complete loss of AR function in males results in complete androgen insensitivity syndrome (Quigley et al. 1995). The role of the AR in the development and progression of prostate cancer has led to increasing interest in this nuclear receptor. Many studies have focused on providing new insights into the mechanisms of AR action in prostate cancer. The determination of the three-dimensional crystal structures of the AR DNA-binding domain (DBD) and ligand-binding

domain (LBD) has helped expand our understanding of this receptor by revealing fine molecular details.

### Mechanism of Androgen Action

Classically androgen show genomic actions via AR-mediated control of gene transcription. This mechanism usually requires at least 30–40 min to alter gene expression and hours to produce significant levels of newly expressed proteins. In the target cell, testosterone diffuses through the lipid bilayer of plasma membrane and interacts with AR bound by a multiprotein complex with heat shock proteins (HSP) and immunophilin chaperones, including HSP90, HSP70, HSP56, and p23. This multiprotein complex is present adjacent to the hormone-binding domain of the receptors and thought to keep the receptor in configuration that is favorable for binding to the hormones and incapable of binding through hormones (Heemers and Tindall 2007). After binding of androgen to the androgen receptor, it undergoes a conformational change, allowing its release from the multiprotein complex. This dissociation unmask AR NLS and dimerization motifs, allowing its increased phosphorylation, nuclear translocation, and homodimerization. In the nucleus, activated AR-ligand homodimer complex binds to specific recognition DNA sequences, the androgen response elements (AREs), localized in the promoter regions of androgen-regulated genes (Avellar et al. 1997; Goodman 2003).

### Nongenomic Action of Androgen

Classical action of androgen is performed via binding through androgen receptors in the nucleus, but some “nongenomic actions” have been also reported via activation of kinase signaling cascades. One well-known example of this action is elevated expression of “prostate specific antigen (PSA)” in prostate via stimulation through dihydrotestosterone. PSA causes cleavage of semenogelin and leads to the

liquefaction of the ejaculate and increases sperm mobility. Its abundance in plasma is widely used as a diagnostic marker of prostate cancer (Goodman 2003).

### Role of Androgens and Androgen Receptor in Sex Development

Androgen also plays a determining role in the development of sexual patterns in embryos during the gestational period. Embryos of both sexes have same developmental pattern till the sixth week of gestation. During this time period, formation of primitive gonads takes place by the migration of primordial germ cells from yolk sac enteroderm to the genital ridge. The primordial urogenital tract of both the sexes contains both Wolffian and Mullerian ducts. The primitive gonads start differentiating into testis at the onset of 6–7th week of gestation. This differentiation comprises of the formation of seminiferous cords and Leydig cells. Regression of Mullerian duct also takes place under the influence of Mullerian inhibiting substance (MIS) that inhibits the formation of female genital structures (Wilson and McPhaul 1996).

The initial differentiation of the testis is directed by SRY gene present on Y chromosome. Further, testosterone produced by primitive Leydig cells leads to the virilization of Wolffian duct structures, and formation of epididymis, vas deferens, and seminal vesicle takes place from 9th to 13th week of gestation. Wolffian duct differentiation requires testosterone and functional androgen receptors; thus, the development of internal ducts of male reproductive system is totally dependent upon testosterone availability in that critical time period of embryo development. On the other hand, development of external genitalia depends upon the availability of dihydrotestosterone (DHT) not on testosterone. Thus in few diseased conditions like “androgen insensitivity syndrome (AIS)” or “complete androgen insensitivity syndrome (CAIS),” the phenotype of the person is of females with normal feminine external genitalia and normal breast development

but internally testis with undeveloped Wolffian duct (Sinclair et al. 1990; Wilson et al. 1981).

## Nonreproductive Function of Androgen

Androgens play various nonreproductive roles also like bone and muscle development. Hypogonadism in male is associated with increased bone loss which is reversed after treatment with androgens (Kang et al. 2003). In skeletal muscle, androgen gets aromatized to estrogen and mediates its action via estrogen receptors. Testosterone also induces muscle growth by increasing satellite cell number along with a proportionate increase in myonuclear number. Eugonadal man, treated with different doses of testosterone, found to show muscular hypertrophy in a dose-dependent manner (Bhasin et al. 2003).

## Conclusions

Various information regarding the mechanism of action of androgens through AR via both genomic and nongenomic pathways are available now, but future investigations and researches are needed to fully elucidate the AR physiological function in male reproduction. More studies are also needed illustrating the roles of selective AR modulators (SARMs) and AR coregulator proteins not only in the more efficient pharmacological modulation of the AR in pathological conditions, such as male hypogonadism, diseases of the prostate, and osteoporosis, but also for the development of therapies for male contraception and treatment of male infertility. Other new approaches like analysis of AR knock-out mice and RNA interference will undoubtedly enhance our understanding of androgen effects on gene expression, especially in androgen target cells and organs.

## Synonyms

[Ad hoc sampling](#); [Focal sampling](#); [Single subject](#)

Anecdotes are descriptions of events or phenomena, usually in narrative form. These descriptions can be true, false, or exaggerated, and anecdotes may be intended as accurate, humorous, engaging, or recountings of unexpected observations. In understanding human behavior and interaction, anecdotes are commonly used to delineate or illustrate character and motivations. In the study of history, anecdotes are used to illustrate events consistent with accepted understandings or to raise questions about these understandings (Gossman 2003). In western cultures, anecdotes about animals have an ancient lineage, with early Roman authors such as Aelian and Pliny the Elder describing intriguing instances (as well as accepted facts) about animal behavior, many

taken from earlier (often Greek) sources. Aelian (2nd–3rd century AD/1958) offers an instance of dolphins escorting a wounded dolphin away from its human captors after scaring them, positing that humans are much less helpful even to their kin (p. 295). Pliny the Elder (1st century AD/1983) describes a hunter who employs tame and wild ravens to capture game and a raven who, to secure rainwater in an urn, drops stones into it to raise the water level (p. 373). Such anecdotes continue to the present day. The medieval era offered anecdotes of animals' crimes and punishments (Evans 1987); anecdotes about animals were also used as allegories for human behavior. Much of the understanding of actual animals provided in anecdotes relied on the acceptance of ideas presented by master scholars such as Aristotle, as well as folk beliefs. However, some medieval scholars examined Aristotle's ideas critically. For example, Frederick of Hohenstaufen, writing in the thirteenth century, questioned Aristotle's knowledge of falconry:

on many points that he [Aristotle] cites in his book *On Animals* he reports that others have reported so, although he may not have seen it himself, nor had his informers seen it. For firm reliability is not produced by hearsay. (Translated in Beullens 2007, p. 146)

Montaigne (1580/1958), in his *Apology for Raymond Sebond*, provides numerous anecdotes about intelligent actions of animals to quell human self-admiration. He provides an example of a fox deliberating at water's edge, reasoning about the sounds of water it hears beneath an ice to determine whether it will support its weight. Although Descartes (1637/1971, pp. 42–43) later denied that examples like those of Montaigne showed anything comparable to reasoning and offered the explanation that animals' actions were instead comparable to actions of machines, his view was not generally accepted by scientists or others, who continued to provide anecdotes of animal intelligence (e.g., Guerrini 2007).

Anecdotes became a scientific problem in light of Darwin's (1871/1896) attempts to support his theory of evolution by natural selection by presenting stories of intelligent action by animals, suggesting a common psychology with humans

(Knoll 1997 in *AAA* (*AAA* refers to the Mitchell et al. (1997) reference, *Anthropomorphism, anecdotes, and animals*, from which are cited several chapters.)). For example, he describes a dog growling at a windblown parasol as indicating aggression derived from reasoning that the parasol was moved by an unseen agency (Darwin 1871/1896, p. 95). Darwin passed on his project of finding and evaluating evidence of animal intelligence to fellow scientist and friend Romanes (1882), who compiled enormous collections of animal anecdotes intended as evidence of mind or intelligence, as indicated by animals exhibiting choice and consciousness (p. 2). Romanes combed scientific and popular literature for facts about animal intelligence, loosely using three principles to determine what to accept as facts: they must be from an authority, the actions described must be distinctive and plausible in relation to the animal's goal (and not subject to an obvious alternative interpretation), and, if possible, they should be observed more than once in the type of animal described in the anecdote (pp. viii–ix). Adhering to these principles was difficult, and Romanes asked not only scientific colleagues but the general public for anecdotes and observations of animal intelligence (pp. x–xi). Although Romanes' anecdotes continue to delight, they lost their appeal for scientists when Morgan (1894, pp. 288–290) argued against their use by showing that what appeared to be intelligent action can derive from unintelligent trial and error. He describes his own dog Tony as, anecdotally, showing signs of intelligence when he lifts the latch of a gate to let himself out. But Morgan had observed the inception of this apparently intelligent action 3 weeks earlier, and the development to Tony's final action was a slow process not based on an understanding of the latch mechanism. Morgan (1894, p. 291) believed that "what we need is careful observation in place of anecdotal reporting"; with such careful observation "we shall acquire a better acquaintance with the psychological processes in animals than we could gain by a thousand anecdotes."

Morgan's claims were supported by Thorndike's (1898/1970) observations of the sequence of animals' attempts to escape when

placed in a "puzzle box": an animal had to perform a specific act to escape from the box and needed to repeat the act to escape when replaced in the box. Thorndike (1898/1970, p. 24) objected to the use of anecdotes, which "report only such facts as show the animal at his best":

Dogs get lost hundreds of times and no one ever notices it or sends an account of it to a scientific magazine. But let one find its way from Brooklyn to Yonkers and the fact immediately becomes a circulating anecdote. ... In short, the anecdotes give really the *abnormal* or *supernormal* psychology of animals.

Contrariwise, observations of individual animals could be used to deny complex cognition in an entire species, as when Pfungst (1911/1965) offered evidence that the horse Hans, who apparently understood how to count, solved problems in arithmetic, and read clocks, was not so clever but was instead responding to body movements of his owner when being questioned about his knowledge. "To remedy [the] defects" of anecdotes, Thorndike (1898/1970, p. 24) remarked, "experiment must be substituted for observation and the collection of anecdotes." Thorndike maintained an indifference to infrequent instances of apparent animal intelligence in his own work, as he never discussed data he presented showing that some cats in his puzzle box solved the problem on the first trial. The view that animals were without intelligence, which Thorndike's experiments promoted but did not always support, was strongly denounced by Mills (1899), who offered an imaginative anecdote to argue against Thorndike's view: he remarks that Thorndike "placed cats in boxes only 20x15x12 inches, and then expected them to act naturally. As well enclose a living man in a coffin, lower him, against his will, into the earth, and attempt to deduce normal psychology from his conduct" (Mills 1899, p. 266). Mills (p. 273) believed that accurate anecdotes were "not valueless" and that "there is no more reason to set aside reliable anecdotes of animals than of men" (1899, p. 262), yet he maintained that "Comparative psychology is advanced rather by systematic observations and experiments than by anecdotes" (p. 273). Washburn (1908, p. 5) delineated the

disadvantages of anecdotal evidence for comparative psychology:

1. The observer is not scientifically trained to distinguish what he sees from what he infers.
2. He is not intimately acquainted with the habits of the species to which the animal belongs.
3. He is not acquainted with the past experience of the individual animal concerned.
4. He has a personal affection for the animal concerned and a desire to show its superior intelligence.
5. He has the desire, common to all humanity, to tell a good story.

Washburn examined one of Romanes' anecdotes (1882, p. 91) which describes ants' burial of the dead in individual graves following a funeral procession; however, when some of the grave-digging ants attempted to escape, these ants were killed and all deposited in a single grave. "No funeral procession for them!" Washburn (1908, p. 9) remarks. According to Romanes (1882, p. 91), "The observation seems to have been one about which there could scarcely have been a mistake"; according to Washburn (1908, p. 9), "One is inclined to think it just possible that there was."

Among naturalists (who wrote for popular audiences, not scientists), anecdotes of observation were commonplace (see Lutts 1990). Burroughs and Muir, by writing of specific encounters with animals and the feelings these engendered, sought to bring out sympathy for animals. Seton and Roberts had observed animals in nature and wrote stories based on their knowledge and anecdotes of particular animals from the animals' perspective. These men often described animals as sharing similar emotional experiences with humans, elaborating the evidence for the emotions in the animals' behavior and context. Muir (1897) provided an extended anecdote of his adventures with the dog Stickeen, who followed him into a snowstorm in Alaska in 1879. As they were making their way back to camp amidst hazardous weather conditions, Muir and Stickeen leapt across many gorges, until one seemed too wide for Stickeen. Muir described

Stickeen's anxiety and refusal to follow him over the expanse, until finally the dog made the attempt and succeeded; Stickeen's joy at his success followed. Seton was a hunter and knowledgeable about animals but also relied on anecdotes he heard to create his stories. Like other naturalists at the turn of the century, Seton believed that anecdotes are valuable and sought evidence from everyday people about animal activities and published their responses. A great deal of the information provided in journals about birds, for example, was from untrained observers (Hayes 1904). Another naturalist, the Reverend William J. Long, wrote numerous books for children based on his own and (mostly) others' observations of wild animals. Long's anecdotes employed an anthropomorphic gloss to understand observations of animal behavior that many believed never happened (e.g., a bird making a cast for its leg injury when it put mud on an injury). Consequently, anecdotes came under scrutiny by other naturalists, particularly Burroughs and then US president, naturalist, and hunter Theodore Roosevelt, who called these naturalists "nature fakers" (see Lutts 1990). For these critics, the main problem was not the anecdote per se (as they were avid users of anecdotes) but rather the falsehoods presented. The same issues that Washburn listed a few years later as problems for scientific anecdotes were acknowledged. Concerns about naturalists' anecdotes appeared in *Science* in 1904. The first letter, by Wheeler (1904), deplored the fact that the public cannot distinguish sound natural history from "drivel in which animals are humanized beyond all recognition," claimed that Long's anecdotes indicated advanced knowledge animals could not possibly have, and noted the "lack of value, which serious students attach to anecdotes as evidences of rational endowment in animals" (p. 348). Others criticized Long as overly imaginative, jumping to conclusions from little evidence, and describing animal behaviors that no one else has observed. The final essay, by Hayes (1904), questioned Wheeler's (1904) analysis of Long's story of woodcock cast making. She claimed that it was Wheeler, not Long, who believed that cast making implies so much knowledge and understanding of theory and asserted

that Wheeler implied “that a man who blows on his fingers to warm them or on his tea to cool it has knowledge of the laws of thermodynamic and is ready to discuss entropy or an indicator diagram” (p. 625).

It is the merest commonplace fact that in order to avoid danger, to lessen pain, to save life, to gain pleasure, human beings are constantly performing acts the underlying principles of which they understand scarcely any better than a woodcock understands the principles of surgery. (p. 625)

Thus, the issues in relation to anecdotes are not only whether or not something happened but how it is to be interpreted if it happened. These issues continue to arise inside and outside scientific circles with people who live closely with animals (see Mitchell et al. 1997).

With the advent of behaviorism in American comparative psychology in the 1920s, concerns about anecdotes as too subjective were extended to all observations of animals, such that any descriptions must be as “objective” as possible, not referring to any mental processes of the animal (Watson 1924). Ethologists and Gestalt psychologists in Europe tended to be less concerned about subjective interpretation and overinterpretation and presumed that adequate description of animal activities required understanding their psychological processes (e.g., goals and emotions) as evident in their behavior (Ellis 1938; Köhler 1925; Mackenzie 1977). Researchers studying apes continued to use psychologically tainted (“anthropomorphic”) anecdotes to derive their understanding of their subjects; indeed, after denying the usefulness of anecdotes of ape behavior prior to behaviorism, primatologists “discovered” the same behaviors occurring among their apes, seemingly unaware that this was rediscovery (Mitchell 1999). Complex psychological terminology (“disgust,” “insight”) in relation to individual activities required not only specification of the animal’s behaviors that implicate the psychological description but also reference to prior related activities that substantiate this interpretation (Köhler 1925). In an attempt to assess the usefulness of anecdotal observations, Hebb (1946, p. 88) examined anthropomorphic observations of chimpanzee behaviors indicating friendliness,

aggression, and threat to determine that a completely “objective” categorization of chimpanzee behaviors led to “an almost endless series of specific acts in which no order or meaning could be found.” By contrast, “anthropomorphic” (i.e., psychological) descriptions of observed behaviors were much more useful as means for keepers and others to know how to interact safely with the chimpanzees.

Throughout much of the twentieth century, a general attitude against anecdotes remained among scientists, which was usually ignored when researchers desired to present anecdotal evidence consistent with current scientific views (usually about apes: e.g., Goodall 1986), but came to the fore when criticizing other researchers’ uses of anecdotes to support different views (e.g., see Mitchell 1993, 1999). Denigration (Keijzer 2013) or elevation (Swartz and Evans 1997 in *AAA*) of animal intelligence could be achieved via an anecdote about one animal that came to be viewed as evidence for the entire species. Initial field research in ethology, and especially in primatology, developed from a sometimes anecdotal methodology to more rigorous observational methods. When Altmann (1974) published her article detailing appropriate sampling methods for specific goals, ad libitum sampling (collecting observations of whatever happens) was viewed as useful only to develop further hypotheses and, perhaps, to learn about rare events. Field researchers in primatology began to use focal animal sampling more extensively, in part supported by sociobiological theory cognizing animals as agents, which led them to interact more directly with animals and, consequently, attempt to take on their perspective (Quiatt 1997 in *AAA*). Such were the attitudes when Griffin (1976) published *The question of animal awareness*, which challenged many accepted interpretations of animal behavior that denied intelligent action. Numerous scientists noted that, but rarely explicated why, anecdotalism was problematic for Griffin’s psychological interpretations of animals’ activities. Still, although scientists can and should find anecdotes about animals engaging, anecdotal descriptions cannot be used to discern the *psychological*

processes that allow for the behavior of apes or other animals (Heyes 1993; Mitchell commentary in Whiten and Byrne 1988, pp. 259–260). When Whiten and Byrne (1988) argued that anecdotes about animals observed by professional primatologists should be accepted as evidence of “tactical deception,” the response from other scientists was mixed, with some accepting anecdotes and others not. Although skepticism was deemed reasonable toward unique anecdotes, Whiten and Byrne (1988) argued that the anecdotes or ad lib observations reported by different observers could be compiled so as to provide multiple records of the same behavior. The term “anecdote” took on new meaning and was now used to refer to a narrative about an observation described by researchers with background and day-to-day knowledge of the nonhuman subjects of the observation (Whiten and Byrne 1988). This methodology only apparently answered many of the earlier criticisms of anecdotes as sources of knowledge about animals’ mental processes (Burghardt commentary in Whiten and Byrne 1988, pp. 248–249). It ignored the need (noted by Morgan (1894), e.g., in relation to his dog’s latch opening) for understanding the larger developmental context (prior behaviors) from which the behaviors described psychologically in the anecdote derive. (By contrast, many animal-language researchers and developmental psychologists, with their extensive knowledge of individual animals and children, contextualized behaviors developmentally for interpretation – see Miles 1997; Mitchell 1997; both in *AAA*; Piaget 1947/1972.) The belief that researchers’ extensive knowledge of animals would derail inaccurate psychological attributions remained unfounded. Whereas several critics remained skeptical that researchers employing anecdotes knew enough to distinguish between more and less complicated psychological explanations for behavior (Heyes 1993; Kummer et al. 1990; Mitchell commentary in Whiten and Byrne 1988, pp. 259–260; Mitchell 1997 in *AAA*), few field primatologists seemed concerned by the use of anecdotes of deception to infer mental state attribution in primates (see, e.g., commentaries following Whiten and Byrne 1988). But if we ignore the issue of whether or not one can attribute

mental states based on anecdotes or observations of nonhuman animals (and there are good reasons to indicate that one cannot: Lurz 2011; contrary to Bates and Byrne 2007), we are left with the fact that observing and naming behavioral patterns within and across species are essential to field studies and have been essential to ethology and comparative psychology from their beginnings (de Waal 1991). As Hobhouse (1901, pp. 89–90) had earlier noted:

In describing the behaviour of an animal, to use terms derived from human consciousness is often the only way of avoiding intolerable prolixity. Properly guarded and corrected by attention to points of difference as well as resemblance, such usage can lead to so little error that, even if we were ultimately to decide that all animals were automata, no change but that of names would be needed in our account. By “feeling” in an animal, then, we shall mean a state essentially similar in causation and function to that which we know as feeling in ourselves. Whether it is similar in other respects, is a question which we do not decide by merely using the term. And so with similar terms.

In our thinking about anecdotes, we seem consistently to rediscover what we already know.

Attempts to formulate a rationale for using anecdotes (observations presented in a narrative) as a source of evidence for an animal’s psychology remain problematic. One suggestion is that if an anecdote is deemed plausible in its description and psychological interpretation, it can count as evidence (Byrne 1997; Rollin 1997; both in *AAA*). But there are often multiple possible psychological interpretations of any given event, such that deciding which one is correct purely from observations is impossible (Lurz 2011; Mitchell 1997 in *AAA*). In addition, plausibility depends on what we currently know about an animal, such that using plausibility as a requirement for the acceptance of an anecdote’s veracity means that anecdotes cannot provide new information, however much they may suggest further research topics. Clearly we need to know the function or goal of an animal’s action if we are to understand it (Millikan 1997 in *AAA*), and anecdotes may provide novel hypotheses as to animals’ goals. Anecdotes are good for illustration of general findings, as in Goodall’s (1986) reframing of anecdotes as

“word pictures.” Summarizing the then recent state of thinking about anecdotes (see also Silverman 1997 in *AAA*), Mitchell (1997 in *AAA*, pp. 426–427) wrote:

Anecdotes by reliable observers can be accepted as believable evidence that specific *behaviors* occurred (this is, that *this* animal did *this* action and *that* animal did *that* action) when these behaviors can be accurately observed under the viewing conditions employed, anthropomorphic terminology can reasonably be used to label or entitle these behaviors, but the interpretation of these behaviors as scientific evidence for mental state attribution demands the same method used to evaluate the accuracy of anthropomorphism: data should be examined using multiple hypotheses varying in the sorts of mental states they propose (if any). As with any science, the accurate interpretation of evidence depends on the hypotheses and perspectives available; and the available evidence may support multiple hypotheses and perspectives. Note, however, that people concerned with ethics toward animals or control of animal behavior, or those just wanting to interact pleasantly with animals, might reasonably use anecdotes and ordinary common sense to fulfill purposes associated with these concerns and desires.

Almost all primate researchers note odd, unexpected, or apparently psychologically complex behaviors in their animal research subjects, perhaps in the hopes of someday understanding them, and sometimes these are reported. But we need to do the same for other species, about whom we are often less willing to construct complex psychological interpretations (Mitchell 1997 in *AAA*). Recent work focuses on whether or not behaviors described in anecdotes can be extended to other species members (e.g., Rutz et al. 2017). Proposed “new” requirements for the collection of anecdotes (Bates and Byrne 2007), where an anecdote is a record of behaviors made by knowledgeable observers soon after their observation, seem to be what researchers have been using all along: the observer must have experience with the animal, must record behavioral observations as soon as possible (and use this record rather than later reminiscences), and must observe multiple instances of the behavior. As noted earlier, this method assures one of the existence of the behavior but offers no reason to believe that individual behavioral observations

themselves, no matter how accurate, can be used to distinguish between complex and simpler psychological processes (Lurz 2011), however suggestive they may be.

## Anger

### ► Benefits for Aggression in Humans

## Angiotensin

Ganesh Kumar Maurya  
Molecular Biology Division, Bhabha Atomic  
Research Centre, HBNI, Mumbai, India

## Synonyms

Angiotenin; Hypertensin

## Definition

Angiotensin (*angio* means “blood vessels” and *tensin* means “increase pressure”) is an oligopeptide hormone in blood plasma that increases blood pressure by vasoconstriction. It is a key hormone of the Renin–Angiotensin system (RAS) in human, which regulates blood pressure and body fluid balance.

In addition to hormone, angiotensin is a dipsogen (an agent that causes thirst) too. It also stimulates the secretion of aldosterone from zona glomerulosa of the adrenal cortex to increase sodium retention by the kidneys.

## Activation and Synthesis

The RAS can be activated in cases when there is loss of blood volume or reduced blood pressure sensed by baroreceptors in carotid sinus. In addition, reduced filtrate NaCl concentration or reduced filtrate flow also triggers RAS activation

by stimulating juxtaglomerular cells of kidney to release renin hormone.

Angiotensin is derived from the precursor molecule angiotensinogen (produced in the liver) under action of renin (kidney hormone) followed by angiotensin converting enzymes (ACE). It finally releases angiotensin in blood plasma for their downstream activity. This system together called Renin–Angiotensin system (Fig. 1).

Types of Angiotensin and Their Roles

Angiotensinogen, a precursor of angiotensin, is a serum globulin protein produced constitutively in liver and released to blood circulation. It is 452 amino acids long in human, where first 12 amino acids (1DRVYIHPFHLVI...452) are required for important biological activity. The first 12 amino acids of angiotensinogen are processed to produce different types of angiotensin.

Angiotensin I

Angiotensin I, also called proangiotensin, is a decapeptide (DRVYIHPFHL) derived from angiotensinogen by the action of renin. Renin is produced in the kidneys in response to reduced blood pressure and NaCl concentration, and cleaves peptide bond between tenth position's leucine (L) and eleventh position's valine (V) of angiotensinogen (Fig. 1).

Roles

Angiotensin I has as such no direct biological activity but it works as a precursor of angiotensin II.

Angiotensin II

Angiotensin II, an octapeptide (DRVYIHPF), is a potent and biologically active form of angiotensin, which produced by removal of two C-terminal residues from angiotensin I via angiotensin-converting enzyme (ACE) (Fig. 1).

**Angiotensin, Fig. 1** Renin-Angiotensin system. The figure summarizes conversion of angiotensinogen (from liver) to angiotensin I and II by renin (from kidney) and

angiotensin converting enzyme (ACE), respectively. Different biological role of angiotensin II has been presented

### Roles

- (a). It acts on the central nervous system (CNS) to stimulate the production of vasopressin.
- (b). It works on smooth muscle of blood vessels to stimulate vasoconstriction (Kanaide et al. 2003).
- (c). Angiotensin II stimulates the secretion of aldosterone from adrenal cortex to retain  $\text{Na}^+$  and lose  $\text{K}^+$  in kidney.
- (d). Angiotensin II also acts on  $\text{Na}^+/\text{H}^+$  exchanger in the proximal tubule of the nephron in the kidney to stimulate reabsorption of sodium and excretion of proton. This also linked to bicarbonate reabsorption. It finally results in an increase in blood volume, pressure, and pH (Le 2012).
- (e). It acts on area postrema and subfornical organ of hypothalamic region in brain to increase thirst sensation (Johnson and Gross 1993).
- (f). It increases the secretion of ACTH from anterior pituitary gland, ADH from posterior pituitary gland (Johnson and Gross 1993), and norepinephrine by directly acting on postganglionic sympathetic fibers.
- (g). It upregulates lipogenesis and downregulates lipolysis (Yvan-Charvet and Quignard-Boulangé 2011).

### Angiotensin III

Angiotensin III, a Heptapeptide (RVYIHPF), is produced by N-terminal degradation of angiotensin II via aminopeptidase A. It shares some of its properties with angiotensin II.

### Roles

- (a). In brain, it acts within neural circuits of the CNS to regulate body fluid balance.
- (b). Like Angiotensin II, it also acts as a vasoconstrictor.
- (c). It stimulates the secretion of vasopressin to control volume homeostasis by reducing renal water loss and increasing blood pressure under conditions of hypovolemia (Reaux et al. 2001).
- (d). It also stimulates aldosterone production and increases mean arterial pressure.

### Angiotensin IV

Angiotensin IV, a hexapeptide (VYIHPF), is produced by N-terminal degradation of angiotensin III via aminopeptidase N. It plays important physiological role in CNS.

### Roles

- (a). Angiotensin IV can improve cognition through effects on acquisition, consolidation, and recall in learning and memory (Braszkowski et al. 1988; Gard 2008).
- (b). It plays role in vasodilation through NO (Mustafa et al. 2001).
- (c). It has shown mitogenic and trophic properties in different cell types (Mustafa et al. 2001).

### Conclusions

Homeostasis of body is required for adaptation in environment. There are many key biological molecules, which play important role in body homeostasis. Angiotensin, a key player of Renin–Angiotensin system, required for body homeostasis during reduced blood pressure or decreased  $\text{NaCl}$  concentration. It maintained blood pressure and  $\text{Na}^+$  in body fluid. Additionally, angiotensin also helps in learning and memory.

## Definition

The animacy effect in memory generally refers to better retention of animates (or information processed as animate) compared to inanimates (or information processed as inanimate).

## Introduction

The adaptive memory framework proposes that memory is tuned to remember aspects of events that are relevant to fitness, that is, that enhance one's chances of survival and/or reproduction. Animates, such as animals and humans, are within the realm of such information because they can be potential prey, predators, mates, rivals, and partners for social interaction, among others (Nairne et al. 2017). Therefore, remembering animate items particularly well (as compared to inanimate items) should be an adaptive feature of our memory systems. Nairne and collaborators put this hypothesis to test a few years ago (Nairne et al. 2013), and various forms of empirical evidence have confirmed that, indeed, people remember animate entities better than inanimates, a phenomenon that has been termed the “animacy effect” (Nairne et al. 2017). In what follows we will briefly describe the experimental procedures that have been used to investigate this effect and some of the obtained results. We will also mention some of the potential proximate mechanisms that have been explored and future directions.

## How It Has Been Studied

Empirical evidence for the animacy effect has been collected using different experimental strategies that can simplistically be classified into item- and processing-based procedures.

*Item-based procedure.* In this line of research, the animacy dimension is determined at the item level, that is, memorability for animate items is compared directly to that of inanimate items. In the original work conducted by Nairne et al. (2013), the authors began by using a pre-existing word database that contained information on various word variables (e.g., imagery and emotionality) as well as on word recallability (Rubin and Friendly 1986). The authors classified those words on animacy, that is, whether each word clearly represented a nonliving thing (inanimate items) or a living thing (animate items). Then, using multiple regression analysis, they explored which word characteristics contributed the most in

**Animacy, Fig. 1** Results of the regression analyses denoting the recall predictors (Experiment 1, left side) and free recall results from Experiment 2 (right side; error bars represent standard errors of the mean) from Nairne et al. (2013)

predicting free recall. Their results revealed that animacy was one of the largest predictors of recall (see Fig. 1). In their second experiment, Nairne et al. preselected a set of animate and of inanimate words. Because words themselves can be characterized on various (other) mnemonic-relevant dimensions (e.g., frequency or imageability), care was taken to ensure that, on average, the two sets of words were equated on those dimensions. Then, participants were asked to memorize the words for a later memory test but were not informed about the animacy manipulation. The results revealed better memory performance for the animates than for the inanimates (see Fig. 1). Given the number of item characteristics that could potentially influence retention, however, item selection problems remained a concern. This led the authors to explore this phenomenon using a processing strategy.

*Processing strategy.* In this procedure, rather than comparing animate with inanimate words, participants are invited to think of new stimuli (e.g., nonwords) as corresponding either to living or to nonliving things (VanArsdall et al. 2013). For example, the nonword “BRUG” if presented

with the descriptor “has a busy schedule” would likely be considered to be a living thing, whereas the word “SMIG” presented with the sentence “needs a battery” would likely be considered to be a nonliving thing. In this procedure, each nonword is equally processed as an animate or inanimate across participants; therefore, the to-be-remembered information is the same in both conditions. What differs is the animacy status it becomes associated with. The animacy effect was replicated using this procedure when free recall or recognition was implemented.

### Evidence for the Mnemonic Animacy Effect

Most studies have used the item-based procedure described above. The animacy effect has been replicated across various laboratories, using different sets of items and in different languages (French: Bonin et al. 2014; European Portuguese: Félix et al. 2019; German: Meinhardt et al. 2018; English: Nairne et al. 2013; Popp and Serra 2018). The procedures have included intentional learning

tasks (i.e., participants are instructed to memorize the presented stimuli) as well as incidental learning conditions in which participants perform animacy-related tasks (e.g., classify the items on their animacy status; Bonin et al. 2015) or other encoding tasks (e.g., pleasantness rating task; Leding 2018); the effect holds under both learning conditions (Félix et al. 2019; Gelin et al. 2017). For the most part, the effect has been demonstrated using short retention intervals, but a recent study has revealed that it holds after a 48 h delay interval (Félix et al. 2019). The effect is also obtained when words and pictures are used as stimuli (Bonin et al. 2014) and when memory is tested in various forms: It remains significant in free recall (e.g., Bonin et al. 2015; Nairne et al. 2013; Popp and Serra 2016; Popp and Serra 2018), recognition (Bonin et al. 2014; Xiao et al. 2016), cued recall (VanArsdall et al. 2015; although see Popp and Serra 2016), spatial and temporal memory (Gelin et al. 2018), as well as metamemory judgments (Li et al. 2016).

### Proximate Mechanisms of the Animacy Effect

Researchers have actively investigated the mechanisms that potentially underlie the animacy effect (i.e., how it is produced). Several possibilities have been considered, including arousal, threat, interactive imagery, attention, or ease of information access. In the first two, it is hypothesized that animates could naturally be more emotionally arousing (Meinhardt et al. 2018; Popp and Serra 2018) or threatening (Leding 2018) than inanimates. However, when animate and inanimate sets of items are equated on arousal and threat, the animacy effect remains. Such dimensions can impact recall, but they cannot completely explain the animacy advantage. In the case of interactive imagery, it has been suggested that animates might naturally afford more imagery processes (as compared to inanimates). However, studies in which imaginative processing was induced, measured, or controlled for, have, as of this writing, also failed to account for the animacy effect (Bonin et al. 2015; Gelin et al. 2019). Other

authors have suggested the existence of an attention bias toward animates (New et al. 2007), which could mediate the memory advantage; however, no strong support for this idea has yet been found (e.g., Xiao et al. 2016). Finally, animates could simply belong to stronger and more accessible semantic categories (as compared to inanimates) facilitating their retrieval. Studies in which targets were masked by intermixing them with other non-related information, controlled for categorical aspects of the items being tested, or measured categorization strategies in the recalled output found no support for such hypothesis either (VanArsdall et al. 2017; see Xiao et al. 2016, for a somewhat related, but different, result). In sum, despite all the proposed explanations, the *how* of the animacy effect remains largely unexplained (Nairne et al. 2017).

### Conclusion

Animates have a privileged status in many aspects of our lives. Children from an early age distinguish animate from inanimate items (e.g., Opfer and Gelman 2011); animates seem to capture attention faster and hold it longer than inanimate items (e.g., Bugajska et al. 2018) and to activate the brain in different ways (Xiao et al. 2016), among others. They also assume a very special status in memory as animates are better retained and remembered than inanimates: the animacy effect. Furthermore, researchers have started to explore applied contexts in which we can take advantage of this mnemonic tuning to improve performance, such as the learning of a new language (Laurino and Kaczer 2019; VanArsdall et al. 2015).

In spite of the robustness of this effect, for the most part, it is still an uncontrolled variable in cognitive research (Nairne et al. 2017). Researchers rarely control for animacy in their selection of stimulus pools. Recently, investigators have been developing norming databases that include animacy (European Portuguese: Félix et al. *in press*; American English: VanArsdall 2016) in order to provide researchers with a useful tool to better select and manipulate animacy in

experiments. However, much more needs to be done to establish animacy as a relevant variable in the memory research field.

## Definitions

### Animal Welfare

Animal welfare has been defined in a multitude of ways. After Ruth Harrison's (1964) *Animal Machines* criticized confinement systems used in industrial animal agriculture, the Five Freedoms were created in order to define the needs of non-human animals (hereafter called animals), needs that if left unfulfilled would result in frustration. The Five Freedoms include freedom from hunger or thirst; discomfort; pain, injury, or disease; fear and distress; and freedom to express normal behaviors. Donald Broom, one of the founders of modern animal welfare science, later defined welfare more simply as an animal's state with regard to their attempts to cope with their environment (Broom 1988). David Mellor later took the definition further into the realm of positive welfare by advocating for provision of "a good life" and "a life worth living," whereby the balance of salient positive and negative experiences is positive (Mellor 2016). This definition of welfare, a culmination of decades of work, relies on understanding which experiences are experienced positively and which are experienced negatively, which leads one to ask how an animal is feeling about those experiences.

## Emotion

To assess whether experiences are positive or negative and hence whether an animal is living a “good life,” caretakers need to be able to assess whether an experience results in positive or negative emotion. Emotions are brief affective responses to an eliciting event and include an expressive component, a physiological component, and a subjective “feeling” experience (Désiré et al. 2002). In the study of human emotion, all three components can be studied, but in animals, the existence of feelings must be inferred based on the presence of behavioral and physiological responses to an event. The presence of emotions in animals is corroborated by research that demonstrates neural biology in different species as similar to that of humans (Désiré et al. 2002). Whereas emotion states are often described as brief, the consequences of those states can be long term with wider ranging welfare impacts, as has been demonstrated by modification of the corticotropic axis in depressive humans, calves, and pigs (Désiré et al. 2002). Historically, research into farmed animal emotion has focused largely on fear. This focus is likely the result of the skewed view of animal welfare generated by the Five Freedoms, which focus on alleviation of negative states, including fear, rather than provision of positive states. The closest the Five Freedoms come to providing experiences that could lead to positive welfare is the need to provide “freedom to express normal behavior.” While intensive animal agriculture often does not allow for even basic normal behaviors, like walking in hens or sows, there is no reason to believe that allowing hens or sows room to walk will provide enough positive experiences to shift the balance of positive vs. negative events in favor of positive. The recent shift in animal welfare science toward positive welfare has resulted in a shift toward measuring positive, in addition to negative, emotions in farmed animals.

## Introduction

Animal welfare assessment requires the collection of a variety of outcome-based measures designed

to assess an animal’s state with regard to health, affective state (i.e., emotion), and the ability to engage in natural behaviors. While all three types of indicators often are incorporated, albeit informally, into welfare assessments of small captive populations, like in zoos, assessment of farmed animal welfare is complicated by population numbers in the thousands or tens of thousands and high stocking densities that effectively obliterate the concept of a farmed animal existing as an individual. For this reason, and likely because the primary goals associated with raising animals for food are not to provide the animals with “lives worth living” but instead are efficiency and productivity, farmed animal welfare assessment techniques have historically focused largely on measures of health. The importance of emotion to accurate assessment of welfare has been clear for years among animal welfare scientists (Boissy et al. 2007) but has yet to be fully integrated in an objective way into farmed animal welfare assessment tools that can be easily and effectively implemented on farm. This article will review the range of emotions present in farmed animals, briefly explore the current state of animal welfare assessment in industrial animal agriculture, identify the extent to which emotion is measured, and assert the need that continues to be expressed among animal welfare scientists to utilize welfare assessments that include indicators of emotion (Wemelsfelder and Mullan 2014).

## Do Farmed Animals Experience Emotion?

The ability to feel emotions underlies the entire field of animal welfare science and thus is a necessary precursor to the development of ethical positions surrounding the exploitation of animals for human use. Investigation into the existence and development of emotionality in farmed animals began as early as the 1960s, when Candland et al. applied open-field testing, previously used to investigate emotions in rats, to explore fear in chickens (Candland et al. 1963). Animal emotion has largely been measured using a dimensional approach. The subjective component of emotion

has two independent dimensions: valence (positive/negative) and arousal or excitation (weak/strong) (Désiré et al. 2002; Vonk et al. 2021). Likely because humans are unable to fully understand the subjective component of emotion in animals, researchers have largely shied away from naming these dimensions using emotions found in humans (happiness, sadness, fear/surprise, and anger/disgust), let alone naming secondary self-conscious emotions in farmed animals (shame, embarrassment, guilt, pride, and envy). Given this, this entry will explore positively and negatively valenced emotions in farmed animals.

### Negative Valence: Fear

Fear, a negatively valenced emotion with high arousal, is the most well-studied emotion in farmed animals, likely because domestication requires a reduction in fear for animals to allow themselves to be in close enough contact with a potential predator (i.e., humans) that they can be subjected to stressful industry standard practices such as tail docking, castration, beak trimming, and disbudding. In addition, animal welfare scientists have sought over the past half century to reduce fear, in line with the Five Freedoms, as a way to improve welfare. Fear has been investigated in farmed animals using novel object tests to measure neophobia, human approach tests, food deprivation, social separation, tonic immobility tests, open field tests, and restraint tests. The expressive component of emotion can take at least three forms: behaviors, vocalizations, and postures/facial expressions.

Chickens have expressed fear through a variety of behaviors including vigilance, tonic immobility, escape attempts, flight from stressor, and distress calls (Baxter et al. 2019; Edgar et al. 2012; Hewlett and Nordquist 2019). Chickens exhibited increased head movements and reduced bouts of comfort behaviors in non-preferred environments, presumably while experiencing negative emotional states, as compared to when they are in preferred environments (Nicol et al. 2011). Physiologically, fearful chickens have been observed to have decreased peripheral temperatures, as compared to baseline

neutral state, as measured in the comb and the eye (Edgar et al. 2012).

The expressive component of fear in cattle has been displayed through immobility, avoidance of the stressor, changes in feeding behavior, and the amount of visible eye whites (Boissy et al. 1998; Bourguet et al. 2010; Sandem et al. 2004). Compared to stressed cows, nonstressed cows exhibited more frequent urination and defecation as well as increased immobility (Boissy et al. 1998). Fear appears to be communicated between individuals. Compared to heifers who were in the presence of a nonstressed conspecific, heifers in the presence of a conspecific who received electric shocks exhibited increased plasma cortisol and increased latency to feed and fed more slowly (Boissy et al. 1998). This study also found that conspecifics responded to the urine of stressed heifers more fearfully (i.e., increased latency to feed and explore, Boissy et al. 1998). Physiologically, compared to baseline levels 3 weeks prior to slaughter, cows at slaughter had increased heart rates and elevated plasma cortisol, urinary adrenaline, and noradrenaline (Bourguet et al. 2010).

Pigs have expressed fear through changes in locomotion levels, freezing, latency to explore novelty, vocalizations (including low-frequency grunts and high-pitched vocalizations), changes in urination and defecation, escape attempts, and attention to conspecifics who have experienced stress and by putting ears back and tail down (Carreras et al. 2016; Goumon and Špinka 2016; Leliveld et al. 2017; Reimert et al. 2017). Pigs who are experiencing negative emotions of low arousal (e.g., sadness) are likely to keep their tail tucked and motionless, whereas those who are experiencing negative emotions of high arousal (e.g., fear or anger) often suddenly tuck their tails (Camerlink and Ursinus 2020). Physiologically, compared to less fearful pigs, fearful pigs who took longer to approach a novel object had decreased dopamine in the prefrontal cortex (Carreras et al. 2016).

### Positive Valence: Happiness

Despite anecdotal behavioral evidence of happiness in farmed animals (e.g., calves frolicking through a field, piglets playing with one another,

etc.), research exploring positive emotion in farmed animals is scarce and is often studied concurrently with negative emotion. Despite the paucity of research devoted to understanding how farmed animals experience positive emotions, it is clear that farmed animals are capable of emotion states akin to happiness. Positive emotions in farmed animals have been assessed using a Pavlovian conditioning paradigm whereby animals learn to associate particular signals with positive (e.g., preferred foods), neutral (e.g., nothing), and negative (e.g., water spray) events; yoked control experiments involving the acquisition of an operant task combined with physiological measures; responses to positive events such as stroking, acquisition of a preferred food item, an enriched environment, or arrival of a conspecific; and observation of the expressive component during play.

The literature on positive emotions in chickens is scarce, which makes sense given that it is difficult for humans to understand emotions in individual chickens when an average chicken barn houses 30,000 chickens. Research has shown that when compared to anticipatory behavior seen prior to negative or neutral events, in anticipation of positive events (i.e., provision of mealworms), chickens expressed positively valenced emotions through comfort behaviors like preening and wing flapping (Zimmerman et al. 2011), standing still, walking slowly, and head bobbing (Moe et al. 2009).

Cattle who experienced success in learning increased locomotion, jumps, bucks, and kicks (Hagen and Broom 2004). Compared to when they were not being stroked, cattle who were stroked relaxed their ears backward or let them hang and decreased the amount of eye white that could be seen (Lange et al. 2020; Proctor and Carder 2015). Physiologically, compared to baseline, cattle presumably experiencing positive emotions had lower nasal temperatures and increased heart rates, but it is not yet clear whether those measures indicate valence or simply a change in valence (Hagen and Broom 2004; Lange et al. 2020; Proctor and Carder 2015).

Compared to pigs experiencing aversive conditions, pigs anticipating and experiencing

rewarding conditions (i.e., straw, peat, and raisins) expressed positive emotion through an increase in play behavior (Reimert et al. 2013). Research has found that pigs communicated positive emotions via shorter grunts with a lower frequency and less noise than pigs communicating negative emotions (Briefer et al. 2019). Piglets produced low-frequency, shorter grunts when they anticipated the arrival of a conspecific and produced higher-frequency, longer grunts when they anticipated the arrival of a human (Villain et al. 2020). Pigs can move their tails and ears, and the way they do so is influenced by the way they are feeling. Pigs who are playing and likely feeling positive emotions often wag their tails. In enriched environments, tails were most often curled up and ears directed forward. In general, a curled tail has been associated with positive emotions of high arousal (e.g., excitement), and a relaxed hanging but loosely wagging tail has been associated with positive emotions of low arousal (e.g., calm, Camerlink and Ursinus 2020). Physiologically, pigs experienced increased heart rate and changes in heart rate variability when they experienced a change in valence (Briefer et al. 2019).

Research on emotion in sheep and goats reveals that they too experience emotions, but a review of that literature is beyond the scope of this entry.

## Animal Welfare Assessment and the Regulatory Framework

While there is room for more research on emotion in farmed animals, there is no doubt that these species feel positively and negatively valenced emotions, likely including fear and happiness, but also potentially sadness, anger, and some secondary emotions. However, even if farmed animals are capable of feeling only positive and negative emotions, it is necessary to include assessments of emotion states when determining whether positive experiences outweigh negative experiences. Despite this knowledge, there are currently no federal laws to protect animals on farm in the United States. The two federal laws that apply to the treatment of farmed animals are

the Humane Methods of Slaughter Act, which exempts the vast majority of farmed animals (i.e., birds and fishes), and the 28-h law, which offers minimal protections for animals in transport. Given this regulatory framework, the animal agriculture industry in the United States is left to police itself with regard to farmed animal welfare, and hence, it should be noted that the following animal welfare assessment techniques are not mandated and may not be used on all farms. Animal welfare laws in the European Union are significantly stronger than those seen in the United States, and hence, these assessment techniques may be utilized more commonly in the EU.

### **Inputs Versus Outcome-Based Indicators of Welfare**

Before examining common welfare assessment techniques, it is necessary to understand the distinction between and importance of input versus outcome-based indicators of welfare. Welfare inputs include those factors that influence the welfare of an animal and include things like food, water, environmental factors, social groupings, stocking density, veterinary procedures, standard mutilations, and breeding programs. Outcome-based indicators of welfare include health measures, gait scores, body condition scores, behavioral measures including activity budgets and the presence of abnormal repetitive behaviors, and indicators of emotion state. It is important to examine both inputs and outcomes when assessing animal welfare. Animal welfare is an attribute of an individual, not a group, farm, or supply chain, and there are significant phenotypic and genotypic differences within breeds of the same species that lead to individual variation in response to those inputs. So while inputs are essential to ensure that the playing field is equal for all animals in a system and should be informed by animal welfare science, it is only through measurements of outcome-based welfare indicators, in at least a representative subsample of a group, that one can determine whether those inputs are providing for a positive welfare state.

### **Animal Welfare Assessment in the United States**

Welfare assessment on farm in the industrial animal agriculture system in the United States focuses largely on health. Whereas good health may indicate a lack of negative emotions associated with health status, it in and of itself does not translate into positive emotion, nor positive welfare. The National Chicken Council's Animal Welfare Guidelines include a variety of inputs designed to "minimize fear, pain, stress, and suffering," including but not limited to limits on stocking density, provision of 4 h of darkness per 24-h period, and environmental ammonia limits. The only on-farm, outcome-based welfare indicator found in the National Chicken Council's Animal Welfare Guidelines is the assessment of gait scores. The US pork industry has a similar set of voluntary guidelines laid out in the Common Swine Industry Audit-Pork Checkoff. Inputs include appropriate animal handling techniques, provision of "adequate space" to 90% of pigs, access to food and water, and whether less than 25% of pigs are electrically prodded during transport loading or unloading. Outcome-based welfare assessment involves daily recording of the number of pigs that have low body condition, severe lameness, tail-biting lesions, rectal and uterine prolapses, umbilical hernias, open wounds, and scratches. Similarly, the inputs included in the voluntary National Dairy FARM Program's Animal Care Version 4 include provision of food and water, protection from the elements, and daily exercise. The outcome-based welfare indicators include body condition scores, the presence of broken tails, hygiene scores, and assessment of lameness.

### **Animal Welfare Assessment in the European Union**

The regulatory framework that protects animals raised for food in the European Union (EU) is laid out in Council Directive 98/58/EC of 20 July 1998 concerning the protection of animals kept for farming purposes, with species-specific

regulations that ensure the welfare of pigs, calves, chickens raised for meat, chickens raised to lay eggs, and cattle. These regulations provide far more protections for animals on farm than are seen in the United States and have been informed by a large body of animal welfare research reviewed by the European Food Safety Authority's (EFSA) Panel on Animal Health and Welfare. Likely to ease enforcement, these regulations are largely input-based. However, reviews of the scientific literature have been commissioned by EFSA through the Animal Welfare Indicators Project (AWIN) regarding the use of animal-based welfare measures (outputs) in animal welfare assessment, and protocols that have come out of these projects do include some measures of emotion state, specifically through Qualitative Behavior Assessment (QBA) (Wemelsfelder 2007).

### Creating a Holistic Assessment of Welfare Through Inclusion of Indicators of Emotion

Negative emotions, which are often expressed in overt stereotypic behaviors, reduced health, and aggression, are already incorporated into routine welfare assessments, whether formally or informally, in animal agriculture (Bracke and Hopster 2006). However, alleviation of negative emotions does not necessarily result in the experience of positive emotions. For this reason, it is necessary to utilize welfare assessment tools like QBA in formal welfare audits and in routine farmer welfare assessments. Informal assessments of positive emotion can be conducted through behavioral observations that assess play behavior, affiliative behavior, self-grooming (although self-grooming can become stereotypical in nature), and the presence of positive vocalizations (Boissy et al. 2007). Assessments must seek to measure the frequency and magnitude of positive emotions and negative emotions; positive welfare results when the time spent in positive affective states exceeds that spent in negative affective states.

### Conclusion

Animals farmed for food experience both positively and negatively valenced emotions, communicated through behavior, ear and tail postures, facial expressions, and vocalizations. Physiologically, farmed animals experience emotion through changes in heart rate parameters, peripheral body temperatures, and hormonal changes. Despite literature confirming a complex emotional experience in these animals, and despite the knowledge that positive welfare is simply a state in which the balance of positive to negative states tips in favor of the positive, the vast majority of welfare assessment tools used in the animal agriculture industry focus primarily on output-based indicators of health, largely ignoring the presence of an inner emotional experience in these animals.

## Introduction

In the neurosciences, animal models play a central role for experimentally investigating neurobehavioral (dys)functions and their underlying (patho)physiological mechanisms and processes. Almost always, when using animal models, one implicitly assumes that they simulate these mechanisms and processes in humans or a species other than the one investigated. These animal models thus focus on the homology/analogy of the behavior and underlying substrates with the final aim to learn about these behaviors and substrates in the species to be modeled. When developing a model or when selecting the most appropriate animal model for a research project, the most important selection criterion is its validity. Validity is the extent to which an animal model's underlying substrates and mechanisms, measurements, and the conclusions drawn from these measurements are well-grounded and represent the real world accurately.

The basic classes of validity, i.e., internal and external validity and face, construct, and

predictive validity, will be discussed, plus additional classes and subcriteria of validity that have been proposed as refinement and extension of criteria for evaluating animal models. Also, different types of animal models and a strategy to evaluate animal models systematically are described.

## Definition

“An animal model with biological and/or clinical relevance in the behavioral neurosciences is a living organism used to study brain-behavior relations under controlled conditions, with the final goal to gain insight into, and to enable predictions about, these relations in humans and/or a species other than the one studied, or in the same species under conditions different from those under which the study was performed” (van der Staay 2006, pp. 133–134).

This definition is followed throughout this entry and is basic to the model development and model evaluation process depicted in Fig. 1.

## Concepts, Mistaken for, and Concepts that Are Closely Related to “Animal Models”

The animal model literature is filled with conceptual confusions about the concepts test and model. They are categories of animal experimentation that have different purposes, different levels of validity, and different epistemic characteristics (see Table 1). Also, the literature sometimes fails to distinguish between a *model organism* and an *animal model*. A model organism is used to study biological phenomena in a target species, due to specific characteristics that include ease of manipulation and reproduction in the laboratory.

Willner (1991) discriminated three main types of animal experimentation in the behavioral sciences – screening tests, behavioral bioassays, and simulations – that are characterized by different uses. The first two fall under the category of **tests**.

## Screening Tests, Behavioral Bioassays, and Simulations

**Screening tests** are used to predict a desired drug activity from which novel candidates can be assessed. They can be further broken down into two subtypes: “First, some are categorized based on their ability to identify drug candidates with a specific type of clinical action. [...] Conversely, screening tests might also target a particular biochemical action or property in order to identify new drug candidates” (Wright 2002, p. 135). Screening tests have two main requirements: that they make exact and effective predictions about the biochemical action of the drug candidates and that they show that the candidates are efficacious in the target species or disorder (Willner 1991). Screening tests require only predictive validity, and the “relevance of the procedure [...] is not an issue, as long as the goal of correctly identifying drugs and drug effects is achieved” (Wright 2002, p. 135). The main use of a screening test is in pharmacological and pharmaceutical research.

**Behavioral bioassays** are used to study the physiological and neurobiological mechanisms that are associated with brain function, being associated with either the evaluation of specific physiological systems or neuronal circuits or measuring dysfunctions produced by experimental manipulations (Willner 1991). Given that behavioral bioassays do not simply seek to develop novel drugs, these types of animal experimentation can have increased explanatory power over screening tests.

**Simulations** generally attempt to model mental disorders based on comparative studies of the same states and conditions (Willner 1991). Simulations are more commonly used to study the pathophysiology and treatment of mental disorders, but they are also useful to produce insights into normal function. Simulations should require the use of animals with pathological organisms and therefore are highly dependent on the criteria and restrictions of validity (see below). *Only a simulation is a proper model, and both screening and behavioral bioassays should be considered “tests.”* While some behavioral bioassays use pathological organisms (e.g., the olfactory

**Animal Models, Fig. 1** The iterative process of model building and model evaluation. (Figure modified from van der Staay et al. 2014 with permission). \*: Here, face, predictive, and construct validities are used as criteria to evaluate a model. However, one may use other sets of validities instead. For examples of additional/alternative

types of validity that could be used to evaluate a model (see e.g., Belzung and Lemoine 2011, Ferreira et al. 2019, and Hoffman 2016). \*\*: If face validity is considered as crucial, failing to meet this criterion should end the model building and evaluation process

**Animal Models, Table 1** A classification of behavioral tests and models based on purpose, epistemic characteristics, and main use

| Category | Type, based on Willner (1991) | Purpose                                                                                                                                                                     | Epistemic characteristics                                                                                                                                                                                                                             | Main use                                                                               |
|----------|-------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------|
| Tests    | Screening tests               | Allows limited comprehension of an isolated aspect of a complex biological mechanism to be mapped<br>Limited predictive usefulness (e.g., predicting desired drug activity) | Underlying biological mechanism does not need to be similar<br>Not necessarily sensitive to, e.g., triggering factors<br>Not necessarily hypothesis-driven<br>Low construct validity; moderate predictive validity (pharmacological isomorphism only) | Drug discovery and screening                                                           |
|          | Behavioral bioassays          | Allows broader comprehension of a mechanism, without necessary causal analogy<br>Moderate predictive usefulness [e.g., studying neural bases of behavioral (dys)functions]  | Biological mechanism is similar, but not causally analogous<br>By definition, is sensitive to disturbances<br>High predictive validity, low to moderate construct validity                                                                            | Investigation of the physiological mechanisms that compose and organize brain function |
| Models   | Simulations                   | Can allow inferences and extrapolation to the human disorder, with high probability that the hypothesis thus generated is true                                              | Similar mechanisms with probable causal analogy<br>By definition, sensitive to disturbances<br>High face, predictive, and construct validity (considers the need to address theoretical constructs on the etiology, symptomatology, and treatment)    | Investigation of the neurobiological underpinnings of a disease                        |

bulbectomy test, in which ablation of the olfactory bulb produces learning deficits, hyper-reactivity, and glucocorticoid responses which are reversed by antidepressants or the stress-induced hyperthermia, in which transferring rats or mice to a novel environment increases body temperature in an anxiolytic drug-sensitive way), it is not *required* of them that the induction methods are analogs of etiological factors of the target disorder. Similar observations can be made for most research on transgenic organisms (e.g., knockout rodents). *Across this entry, “animal model” will be used interchangeably with “simulation.”* Table 2 provides a non-exhaustive overview over different types of model animals and of the dependent and independent variables in animal models.

## Biological and Clinical Relevance

An important criterion for using a behavioral model is biological and/or clinical relevance (van der Staay 2006). Relevance can be determined using many different criteria (van der Staay 2006), all of which depend on the purpose of the model, the information available for the evaluation, and the stage of development of the model (see Fig. 1). Thus, tests and models have different uses, which should be explicitly defined at the outset: “The explicit definition and designation of the specific purposes that an animal model should fulfill is basic as it allows to define a set of weighted criteria for evaluating the model” (van der Staay et al. 2009, p. 2). Many different uses of a model, and the differentiation between tests

**Animal Models, Table 2** Types of model animals and the independent and dependent variables in animal models. (Modified from van der Staay et al. 2009, p. 4. Table 1A, B). Part A lists different types of “model animals” for the

study of behavioral dysfunctions (inspired by Gamzu 1985). It focuses on the type of subject (independent variable) and is not concerned with the type of dependent variable measured

A: Types of “model animals” (note that the list of models is not exhaustive)

| “Normal” animals, i.e., animals without any observable behavioral deficit. (Studying behavior in “normal” animals provides the baseline data for identifying abnormal behavior)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | Animals with naturally occurring neuronal deviations, neuropathologies, or neurological/psychiatric (endo)phenotype(s)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | Animals with experimentally induced behavioral dysfunctions or characteristic behavioral (endo)phenotype(s)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <p>Note: At first glance, normal animals are not model animals for the study of, for example, neurobehavioral disorders. Normal animals are used to:</p> <ul style="list-style-type: none"> <li>• Assess the safety/toxicology risk of a putative therapeutic;</li> <li>• Obtain an estimate of the putative abuse liability of a compound</li> <li>• Explore the neurobiological specificity of compounds and their molecular and cellular mechanisms of action</li> </ul> <p>Isogenic populations, for example:</p> <ul style="list-style-type: none"> <li>• Monozygotic twins or multiples</li> <li>• Clones</li> <li>• Inbred strains and variants; coisogenic strains (differing at one single locus); Coisogenic strains (differing by a mutation at a single locus); congenic strains, (differing at only one locus and a linked chromosomal segment); recombinant inbred strains (with a permanent set of recombinations between chromosomes from two or more inbred strains)</li> </ul> <p>Non-isogenic populations, for example:</p> <ul style="list-style-type: none"> <li>• Random bred and outbred strains; animals caught in the wild</li> </ul> | <p>Spontaneously and endogenously occurring psychiatric or neurological conditions; spontaneously occurring mutations; aging animals</p> <p>Genetic lines: Inbred strains and their crossings</p> <p>Selection lines, established through artificial selection favoring low and/or high values of a particular trait within a given population for a number of successive generations; preferentially including an unselected control line for comparison</p> <p>Selected extremes from a particular animal population, e.g., good vs. poor learners, dominant vs. subordinate animals, non-aggressive vs. aggressive animals; anxious vs. bold animals</p> | <p>Transgenic and knockout animals; isogenic or non-isogenic populations that express a neurobehavioral deficit or a neurological/psychiatric (endo)phenotype</p> <p>Animals from mutagenesis screens (after thorough phenotyping and validation)</p> <p>Selection lines resulting from selective breeding</p> <p>Environmental factors: e.g., animals experiencing acute or chronic stress, pain, or sleep deprivation</p> <p>Animals with disruptions induced by:</p> <ul style="list-style-type: none"> <li>• Dietary composition (e.g., tryptophan depletion)</li> <li>• Pharmacological compounds (e.g., scopolamine, MK-801), or</li> <li>• Electrically, or by hypoxia, or anoxia</li> </ul> <p>Animals with focal or global ischemic, embolic, or hemorrhagic cerebral stroke</p> <p>Animals with CNS-specific lesions, for example: neuro- or immunotoxic lesions; lesions induced by aspiration, ablation (knife cuts); radio-frequency lesions, cryogenic lesions</p> |

B: Independent and dependent variables

| Independent variable (in essence the model animals and their controls listed in part A)                                                                                     | Dependent variables and/or (endo)phenotypes                                                                                                                                                                  |                                                                                                                                                                |
|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                                                                                                                                             | Neuropathological changes                                                                                                                                                                                    | Behavioral changes                                                                                                                                             |
| E.g., genetically modified animals, aged animals, lesioned animals, ischemic animals, hypoxic animals, aged and lesioned animal, i.e., combination of deficits (see part A) | Damage or dysfunctions induced: Site and size of neuronal damage (neuropathology), effects on specific neuronal circuits or neurotransmitter systems, psychophysiological and/or biological (endo)phenotypes | Behavioral dysfunction or malfunction: Impaired cognitive performance, impaired sensorimotor functions, neuropsychiatric symptoms, behavioral (endo)phenotypes |
|                                                                                                                                                                             | Homology of damaged area(s) or neuropathological changes.                                                                                                                                                    | Homology of disrupted processes or impaired functions                                                                                                          |
|                                                                                                                                                                             | Operational definition(s) of the neuropathological (endo)phenotype(s)                                                                                                                                        | Operational definition(s) of the behavioral (endo)phenotype(s)                                                                                                 |

(screening, bioassays) and models (simulations), suggest that “(…) the value of an animal model is relative, not necessarily to the degree that it simulates the structural, functional, and behavioral correlates of [psychopathology], but to the degree that it comports with the specific tasks for which it is being used. The aims of neuropsychopharmacological research are heterogeneous, often being contextually calibrated to fit specific needs and questions of a wide variety of researchers. Consequently, acknowledging the proper roles and capacities of animal models, and not overgeneralizing or wresting them from their intended domains of application, is therefore a major step in arresting criticism pertaining to the legitimacy and logistics of animal modeling” (Wright 2002, p. 134).

An important consequence of that formulation is that “relevance” is always relative to the aims of the research and not an a priori property of the model. “Relevance reflects the meaningfulness and usefulness of results obtained with an animal model for a particular scientific and/or clinical purpose” (van der Staay 2006, p. 146). The purposes of a model are to enhance our understanding of the underlying substrates and mechanisms associated with the disorder and to assess the effects of drugs and treatments in a different system than the target population (e.g., the patient) (Maximino and van der Staay 2019; van der Staay 2006), allowing inferences and extrapolation to disorder in a certain target species, with high probability that the hypothesis that is generated by the model is true (Maximino and van der Staay 2019). However, a model may have a more limited applicability but still may be relevant for specific purposes (van der Staay et al. 2009).

While the concept of relevance is central to this formulation of behavioral models, it is sometimes confounded with the concepts of validity (see below). Thus, models possess relevance if they are valid and generalizable (van der Staay 2006). Since behavioral bioassays and screening tests do not require construct validity, their relevance lies in their sensitivity to find novel therapeutics (in vitro and in vivo) and/or in their capacity to generate novel hypotheses on normal and pathological brain functioning.

## Model Building as an Iterative Process

The aspects discussed so far draw attention to an implicit aspect of the use of animal models, viz., that model building is an iterative process. Therefore, it is sometimes difficult to judge whether a model is established (i.e., that it satisfies the preset validation criteria) or whether its developmental process is reaching a dead end because it fails to meet essential validation criteria (see Fig. 1). The central role of theory in construct validity (Maximino and van der Staay 2019), as well as the importance of the *zeitgeist* in the creation of a model, creates the necessity to make the theoretical basis of the model explicit. All model development begins with a hypothesis derived from data or theories (van der Staay 2006). Model building proceeds from this hypothesis-building stage to a **selection stage**, in which aspects of normal or abnormal behavior of the species to be modeled are selected. “This stage thus reflects the intended animal model and its first translation into testable behavior that is believed to be indicative for the behavioral (dys)function to be modeled.” (van der Staay 2006, p. 142). The next step in the model building process is a **consensus stage**, in which the criteria, definitions, and assumptions regarding the validity of the analogy are discussed and agreed upon. The following stage, the **deduction stage**, involves the decomposition of the endophenotypes under analysis and the verification of the translational relevance (i.e., whether the same endophenotype can be tested in both the model and the target) (Fig. 1). These steps are mostly theoretical and are followed by the **model building stage** per se (van der Staay 2006).

Probably the most important stage in this process is the **model evaluation stage** (Fig. 1), in which the results obtained with the model are evaluated (van der Staay et al. 2009). The many different proposals for evaluation strategies will be discussed in the next section. If the model is considered acceptable after this stage, the process enters an **induction stage**, in which knowledge gained from the experiments performed to develop and validate the model can be used to further refine or correct the concepts which sustain the model; otherwise, the researchers should

determine whether the failure was due to choosing inappropriate criteria to build the model or whether the criteria need to be refined.

Note that not all criteria can be evaluated in a single experiment. Testing replicability, for example, needs data from at least two experiments. For the time being, therefore, one may assume that a criterion is fulfilled, until enough evidence has been accumulated (i.e., after a number of experiments have been performed) to base the decision about whether a particular criterion is met, or whether the model fails to meet a criterion, on scientific evidence.

## Model Evaluation and Concepts of Validity

### Basic Classes of Validity

Concepts of validity are highly variable between model theorists (Belzung and Lemoine 2011; Ferreira et al. 2019; van der Staay 2006). While most follow the recommendation of using face, construct, and predictive validity as the main or essential criteria for evaluating a model, many other propositions appeared; Table 3 attempts to summarize these suggestions, which are detailed in what follows.

**Animal Models, Table 3** Concepts of validity, their definition, and their relations. (Adapted from Belzung and Lemoine 2011, Maximino et al. 2010, McOmish et al. 2014, and van der Staay et al. 2009)

| Validity concept    |                                                | Definition                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|---------------------|------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Internal validity   | Replicability                                  | “The degree of accordance between the results of the same experiment performed independently in the same or different laboratories” (van der Staay et al. 2009, p. 3)                                                                                                                                                                                                                                                                                                   |
|                     | Reliability                                    | The overall consistency of measurements made using the model                                                                                                                                                                                                                                                                                                                                                                                                            |
| Face validity       | Ethological validity                           | Similarity of behaviors in normal and pathological organisms (Belzung and Lemoine 2011)                                                                                                                                                                                                                                                                                                                                                                                 |
|                     | Biomarker validity                             | Also an aspect of convergent validity; whether biomarkers associated with the disease also appear in the model (Belzung and Lemoine 2011)                                                                                                                                                                                                                                                                                                                               |
| Predictive validity | Pharmacological isomorphism/remission validity | A given drug effect being characteristic for a well-defined class of chemicals and indicative of a specific mode of action                                                                                                                                                                                                                                                                                                                                              |
|                     | Induction validity                             | “The action of the etiological factors on the observable effects of the model disease resemble its action on the observable effects of the human disease” (Belzung and Lemoine 2011, p. 9)                                                                                                                                                                                                                                                                              |
| Construct validity  | Homological validity                           | Whether the trait in question is homologous in humans and the species tested (Maximino et al. 2010)                                                                                                                                                                                                                                                                                                                                                                     |
|                     | Genetic validity                               | Similarity of the genetic or genomic basis for the endophenotype / disordered domain                                                                                                                                                                                                                                                                                                                                                                                    |
|                     | Environmental validity                         | Similarity of G x E interactions (McOmish et al. 2014)<br>Ontopathogenic validity: similarity of “early environmental factors whose interaction with the initial organism produces a vulnerable organism” (Belzung and Lemoine 2011, p. 7); triggering validity: “the similarity of triggering factors occurring during adulthood whose interactions with either a vulnerable or an initial organism produces a pathological organism” (Belzung and Lemoine 2011, p. 7) |
|                     | Mechanistic validity                           | Similarity of the mechanism one supposes or knows is working in the animal disease to the mechanisms that is presumed to be working in the human disease                                                                                                                                                                                                                                                                                                                |
|                     | Pathogenic validity                            | Similarity of the processes that lead to disease                                                                                                                                                                                                                                                                                                                                                                                                                        |
|                     | Inter-relational validity                      | Ability of the proposed model to target the interplay between various disordered domains (Stewart and Kalueff 2015)                                                                                                                                                                                                                                                                                                                                                     |
| External validity   | Convergent validity                            | Similarity of results from different methods                                                                                                                                                                                                                                                                                                                                                                                                                            |
|                     | Translational value                            | Ability of the proposed model to produce results which are translated to the target disorder                                                                                                                                                                                                                                                                                                                                                                            |

### Internal Validity and Reliability

Among the proposed methods for evaluating a model is the assessment of its reliability and replicability. **Reliability** is primarily a property of the method, while **replicability** is a property of the results obtained using a particular model. The first, then, indicates how consistent the method is or the extent to which the model yields consistent results each time that measurements are performed under the same conditions. In animal modeling, reliability refers to at least three different properties: the replicability of the model in different laboratories; the concordance of measures taken by different independent observers or by different methods (e.g., automated vs. manual data collection); and the evaluation of the temporal stability of the behavior measured. The concept is conflated with replicability, “the degree of accordance between the results of the same experiment performed independently in the same or different laboratories” (van der Staay et al. 2009, p. 3). Indeed, test theory identifies several classes of reliability estimates (inter-rater reliability, test-retest reliability, inter-method reliability, internal consistency reliability) which are sometimes related to replicability.

Both reliability and replicability are part of the **internal validity** of an experimental method (Table 3; Fig. 2), a characteristic of “how well a study was performed, how strictly putative confounding variables were controlled, and how confident one can be that the changes observed in the dependent variable(s) are *caused* by

experimentally manipulating the independent variable(s), and not by confounds” (van der Staay et al. 2009, p. 3). Internal validity refers mainly to the need to objectively, reliably, and replicably measure the phenomena being evaluated; therefore, it refers to the consistency of the experimental design (Belzung and Lemoine 2011) and the reduction of biases through randomization and blinding (Ferreira et al. 2019) as sine qua non conditions for external validity. Strictly speaking, internal validity is also about causality (van der Staay et al. 2009).

### Face Validity

**Face validity** refers to whether the test has a perceived resemblance to its target – whether it “looks like” its target. One important limitation to the attempt to establish face validity as a point-to-point correspondence between a disorder and an animal model is “the fact that there is no good reason to suppose that a given condition will manifest itself in identical ways in different species” (Maximino et al. 2010, p. 117). The presence of a symptom in itself has no value if it is not assumed to indicate the expression of an underlying pathological condition, and many authors consider face validity of lower significance for the evaluation of a model (McKinney and Bunney 1969; van der Staay et al. 2009).

Discarding direct references to symptomatology and focusing on neurobehavioral alterations that are distinctive of a given disorder increases face validity because it allows for the use of a

**Animal Models, Fig. 2** Face, predictive, construct, and external validities are the basis for animal model development and model evaluation (see also Fig. 1). In addition, in experimental approaches, two classes of validity may be distinguished: internal and external validity. The bidirectional and recursive relationship between animal models,

translation to applications, and reverse translation to animal models is indicated by the two-headed arrow to translational research. Insights gained in the translational stage may also feedback (reverse translation) to the model building and model evaluation process

given *endophenotype* that is observed in both species. For example, schizophrenic patients have deficits in working memory, attention, and sensorimotor gating that are not part of the diagnostic criteria; since sensorimotor gating can be assessed via measures of prepulse inhibition (PPI) of the startle reflex, decreases in PPI in nonhuman animals are often used as evidence for face validity (Gould and Gottesman 2006). This strategy shifts attention toward other variables, but the functional significance or the specificity of the endophenotype is not a requirement for its definition. For example, not all schizophrenic patients show PPI deficits, and PPI alterations can be found in other neuropsychiatric diseases.

Face validity is also increased by focusing on cross-species psychological processes, a strategy that “(…) requires prior extensive research on the biology and ethology of these species” (Belzung 2014, p. 1044), and is referred to as **ethological validity**. Ethologically valid models use endpoints that are functionally meaningful, serving the same *function* as the target behavior, domain, or endophenotype. Perhaps no field has focused so much on this as the field of anxiety research (Maximino et al. 2010).

Belzung and Lemoine (2011) proposed that face validity is associated with both ethological validity and **biomarker validity**: “The former is the similarity of behaviors related to the presumed pathological organism. Here again, the meaning matters more than the material similarity. Biomarker validity is the similarity of biological markers related to the presumed organism. What matters is the function of a marker, not its chemical composition” (Belzung and Lemoine 2011, p. 9).

### Predictive Validity

**Predictive validity** relates to the success of predictions derived from the model. Willner (1991) emphasized that predictive validity also includes McKinney’s and Bunney’s (McKinney and Bunney 1969) “similarity in treatment effectiveness”; in that sense, predictive validity reduces to *remission validity* or *pharmacological isomorphism*. While theoreticians for model building agree that predictive validity is less important than construct validity (van der Staay 2006; van der Staay et al. 2009), in

practice most researchers appear to consider pharmacological isomorphism as more important (Maximino et al. 2010). Pharmacological isomorphism also requires that drugs which are *not* effective in clinical settings do not affect the model (i.e., no errors of commission are present); for example, amphetamines are commonly used in pharmacological validation of anxiety models because they do not reduce anxiety, but can produce “false positives” by altering locomotion (Willner 1991). The appeal to pharmacological isomorphism, usually without reference to construct validity, weakens the operationality of the model and risks circularity in the definition; for example, defining an outcome in the EPM as anxiety-like because anxiolytic drugs decrease it, although a common practice, is circular definition.

Pharmacological isomorphism can be an important criterion for screening tests and behavioral bioassays, but it is not sufficient for a simulation (Willner 1991).

In addition to showing responses to clinically effective drugs, predictive validity of proper models requires that the model is responsive to drugs and treatments that exacerbate the same symptoms and that the model is responsive to all classes of drugs that are useful in treating the target disorder instead of being only sensitive to the effects of drugs with specific pharmacological characteristics (e.g., structure-activity studies) or show only narrow effects on specific neuronal functions (e.g., serotonin reuptake inhibitors). Also, predictive animal models should be sensitive to the relative potencies of different drugs corresponding with their potencies in clinical use (Ferreira et al. 2019). Moreover, simulations are less sensitive to false positives and false negatives than screening tests and behavioral bioassays: “False positives may be clinically effective at high doses, but go unnoticed due to the desire to stave off dire side effects. On the other hand, false negatives raise the possibility of clinical subgroups and populations with differing response patterns” (Wright 2002, p. 137).

### Construct Validity

Construct validity refers to the theoretical rationale behind a given model. The most influential

description of construct validity in animal modeling is that of Willner (1986), who proposed five subcriteria for a model to have construct validity: “[w]hether both the behavior in the model (1) and the features of [the disorder] being modeled (2) can be unambiguously interpreted, and are homologous (3), and whether the feature being modeled stands in an established empirical (4) and theoretical (5) relationship to [the target disorder]” (Willner 1984, p. 1).

### Subcriteria for Construct Validity

There is no consensus about what exactly Willner’s (1984) sub-criterion 5 entails. Atanasova (2015) suggests that construct validity “requires proper mapping between the hypothesized mechanisms underlying the human and the animal behaviors respectively” (Atanasova 2015, p. 172). Belzung and Lemoine (2011) argued that the theoretical relationship between model and target is understood in a polysemic sense, including theories about the nature of the disorder; the centrality of a dysfunctional process to the disorder (e.g., helplessness and anhedonia are central symptoms of depression, and fear generalization is a central aspect of PTSD, etc.); the dynamic of the disorder (time course, relationship to previous stress, etc.); and etiological aspects. Etiological aspects, in turn, include theories on the role of triggering events in causing the disorder in human patients and in animal models (e.g., stress may cause depressive-like symptoms in animal models and major depressive disorder in humans); the centrality of specific characteristics of these triggering events (e.g., stressor uncontrollability, intensity, or distance to threat); and the involvement of associated biological processes (e.g., dysfunctions in the brain reward system or the fear system).

Another important aspect of the theoretical grounding of construct validity is that properly developed theories can provide the model with stronger predictive and face validity (McNaughton and Zangrossi 2008). As a consequence, novel models generated directly from a theory can provide “a range of constructs from which a suitable model can be extracted by design” (McNaughton and Zangrossi 2008, p. 17).

The influence of the *zeitgeist* is especially important when considering the theoretical basis of construct validity. It has been argued that the theoretical choices that constrain model building should not be understood as homological – that is, “the choice for a model based on operant or respondent behavior, in a naturalistic situation or related to pharmacologic (sic) manipulation,” should not imply that the pathology that is modeled is reducible to these mechanisms (Gouveia and de Brito 2015, p. 308). Nonetheless, theoretical considerations are very important in model building: “Model-based science is an exercise in *theorizing* or speculating on unknown mechanisms and outcomes. Modeling is always an indirect type of theory-building practice” (Degeling and Johnson 2013, p. 95). A properly developed theory encapsulates a network of data and other theories, and by capturing the “essence” of this network, the construct is validated (McNaughton and Zangrossi 2008).

One central theoretical assumption of animal models is that of homology between model and target, in the evolutionary sense (Greek and Rice 2012). The (usually unspoken) assumption is that, since mental (and nonmental) disorders represent an extreme in a continuum, the trait/phenotype/domain of interest is conserved between healthy humans and other species. For example, it has been proposed that “normal” anxiety is an adaptive response that is part of the defensive repertoire of the animal. The obvious consequence is that the normal defensive repertoire of a given animal can be used to study “normal,” non-pathological anxiety (or at least some aspects of anxiety), as well as normal fear-like behavior. That is the concept of **ethological validity** proposed by Belzung and Lemoine (2011). Usually, however, the conservation is implied but never tested (Maximino et al. 2010). Moreover, which endpoint to choose cannot be so easily determined for other domains that are dysfunctional in several disorders, such as cognition.

### External Validity, Standardization, and Generalization of Tests and Models

In addition to the earlier described well-accepted criteria, other researchers have suggested the application of additional validity criteria to

improve the ability of animal models to identify novel drug targets (which is not the same as enhancing the analogy). Thus, genetic validity, environmental validity, and population validity have been proposed as important criteria (Hoffman 2016). These are special cases of **external validity**, which “involves an inference to the *robustness* of a causal relation outside the narrow circumstances in which it was observed and established in the first instance” (Guala 2003, pp 1198–1199, emphasis in the original). In that sense, external validity is a consequence of construct validity.

The establishment of the external validity of a given model is not straightforward; evaluation of generalizability is usually understood as the last step in the model evaluation stage (Fig. 1). While epistemological discussions on external validity usually rely on subject and laboratory conditions (Guala 2003), in the case of animal models, the tests for external validity rely on whether the model possesses validity across different housing conditions and laboratories or across different behavioral tests that are believed to measure the same underlying traits and whether the model enables insights and predictions to other species (van der Staay et al. 2009).

### Genetic and Environmental Validity

**Genetic validity**, as proposed by Kas and colleagues (2007), refers to whether there is an identical genetic basis for the endophenotype – that is, whether the genes that determine behavior in the model are also associated with the target disorder and shared between humans and the model organism. The use of behavioral domains (endpoints or endophenotypes representative of naturally occurring behavioral functions, such as social interaction, appetitive motivation, memory function, and emotionality) is similar to the “research domain criteria” (RDoC) approach proposed by the NIMH (Cuthbert 2014). In this case, the focus is not on altered (dysfunctional) endophenotypes, but instead on naturally occurring behavioral domains that are relevant to both animal behavior and human neuropsychiatric disorders. It is expected that “inter-species trait genetics rather than complex syndrome genetics will optimize genotype-phenotype relationships for

neuropsychiatric disorders and generate powerful new disease models that will facilitate the identification of biological substrates, their developmental consequences, and the environmental modulators underlying these disorders” (Kas et al. 2007, p. 324).

To increase the genetic validity, it is important to model a disordered domain across numerous species (Kas et al. 2007), largely based on the notion that behaviors and their genetic underpinnings are evolutionarily conserved across different species because of common adaptive mechanisms (Greek and Rice 2012). An important limitation of this approach is that genetic validity cannot be properly established for a wide variety of endophenotypes and genes. For example, some genes and behaviors do not correlate across species (LaPorte et al. 2008) – especially considering nonmammalian species, which show different number of genes encoding specific proteins. Moreover, the individual domains and endophenotypes which are analyzed may only incompletely model the target disorder, and in this case, genetic validity can only be established as an accessory argument after construct validity has been established. Finally, genetic analyses in animals usually demand isogenic lineages based on inbred strains, but the human population is genetically heterogeneous, and therefore using only inbred animals decreases external validity (see below) (Stewart et al. 2015).

**Environmental validity** adds a novel layer to the complexity of genetic validity in requiring that not only gene variants can be identified in both the model and the target disorder but that specific gene by environment interactions can be found for both cases (McOmish et al. 2014). In particular, behavioral models could benefit from “a complementary ‘enviromics’ approach, in which the ‘envirome’ contributing to the pathogenesis and progression of each disorder, and multiple disorder (‘environmental pleiotropy’), is systematically catalogued and computationally analysed” (McOmish et al. 2014, p. 4723).

The same critique made for the role of etiology in establishing validity can be made for both genetic and environmental validity, though, usually, it is precisely the genetic, genomic, or “enviromic” underpinning of the disorder that is

under study with the model, and therefore it is not known beforehand. A solution to this conundrum is assuming that both genetic and environmental validity are “accessories” in establishing external validity and are in fact practical consequences of using different species to test hypotheses. Indeed, the idea that gene by environment relations are important to the establishment of psychiatric disorders has a rich theoretical background that must be taken into consideration when assessing a model’s validity (van der Staay 2006).

Another approach to environmental validity is to consider whether standardized housing appropriately models the conditions in which target species (humans and nonhuman animals) usually live. What usually is referred to as “standard housing conditions for rodents” is in fact barren environments that produce animals that are metabolically morbid, and the environments in which animals are reared lack sensory, cognitive, and motor stimulation (Burrows et al. 2011). This, of course, contrasts with the majority of humans who receive a wide range of sensory, cognitive, and motor stimulation throughout their lifetimes: “The implicit argument here is that the conditions under which laboratory rodents are kept are well below what any wild animal in its natural environment might experience and, having observed the dramatic effects of marginally enriched environments upon the brain chemistry of these animals, we cannot ignore the possibility that a brain which enjoys even some basal level of stimulation (such as a mouse with even minimal levels of enrichment and/or the majority of humans, and thus the target population we are attempting to model) may be predisposed to respond differently to the therapeutics which are being tested preclinically than mice housed under standard conditions” (Burrows et al. 2011, p. 1380).

Important experimental confounds can be thus introduced, reducing the internal validity of the model; moreover, a model that is applied to animals reared in impoverished environments lacks construct validity (Burrows et al. 2011). While concerns on behavioral variability generated by environmental enrichment, as well as increases in cost and space needs, are common difficulties in most research settings, it has been proposed (Burrows et al. 2011; McOmish et al. 2014) that

a secondary screen is added to the set of experiments in order to test whether a given intervention that was shown to have efficacy under barren housing conditions also has effects in animals housed under enriched environments.

### Convergent Validity

One important aspect of external validity, in the case of animal models, is **convergent validity** (Atanasova 2015). This refers to the ability of results to converge (or at least be compatible) with results obtained with different methods that measure similar traits. Most guidelines for reporting or conducting in vivo animal research make recommendations regarding convergent validity, insisting on replication in different models of the same disease (e.g., different transgenics, strains, or lesion techniques); independent replication by different researchers or, ideally, research groups; and replication on different species. For example, in behavioral genetics it is common to demonstrate that knocking out a given gene produces alterations in more than one behavioral model. In behavioral models with several dependent variables, convergent validity is harder to establish, since the variables do not necessarily measure the same underlying construct (see above). In that case, a variety of multivariate statistical methods can be used to establish the underlying factors/traits that are shared by different dependent variables across tests. Factor-analytical, hierarchical clustering, multitrait-multimethod tests, animal model arrays, and multidimensional scales are useful in that direction (Maximino et al. 2014).

Perhaps more important than convergent validity is the need to increase translational value, the ability of a given model to produce results that are translated to the target condition/disorder. While drug development is not the only aim of animal modeling, the success rates for drugs which move in the production pipeline from preclinical to clinical research remain low, despite important advances in the use of high-throughput approaches to target identification. Belzung (2014) identified four “drawbacks” in current model research that decrease translational value: lack of homological validity; lack of pathogenic validity; lack of refinement of preclinical

situations; and predictions from animal models not taken into account when translating findings to the target disorder. In addition to these limitations, the inability to translate has been associated with differences in treatment modalities, when delays to start treatments that are unrealistic in the clinic are applied in the model; when the dose range used in the model is unfeasible in the clinic due to toxicity or reduced tolerability; or when differences in the timing of testing exist between animal studies and clinical trials (e.g., by using acute versus chronic treatment). Important factors for pharmacological research include treatment initiation time, duration, and frequency, as well as endpoint evaluation time (Stewart et al. 2015). The lack of pathogenic validity, for example, can occur due to the induction of the disease in animals that are healthy when the disorder occurs mainly as a comorbidity; to the use of homogeneous groups of animals, when the disorder affects a heterogeneous group of patients; or to the use of male animals when the disorder occurs mostly in female patients. Most of these recommendations rely on knowing aspects of the disorder that are relevant to the model and incorporate epidemiological data on the model. Thus, the external validity of a model will largely be determined by disorder-specific factors.

### External Validity and Standardization

Recently, the low external validity of animal models, particularly in pharmacological research, has been thoroughly discussed, and solutions to increase it have been proposed. The need to standardize procedures has also recently extensively been discussed. One criticism was that task variations sometimes are introduced to study specific aspects of the disordered domain, and therefore using standardized tasks can preclude these specific uses. Stewart et al. (2015) made methodological recommendations for anxiety research that can be applied to a wider field. They recommend focusing on multiple endophenotypes or endpoints, expanding beyond the usual breadth of tests which are common for a disorder. Stewart and co-workers (Stewart et al. 2015) also recommend including a panel of outbred strains to increase “population validity,” considering the genetic variability of human populations. They

also recommend using “smart” test batteries and considering a wider spectrum of drug regimens beyond the “classical” acute and chronic treatments, including the addition of intermittent treatment, subchronic treatment, and early or late treatment initiation times and the introduction of delayed response evaluations (e.g., assessing results several weeks after treatment initiation). Finally, they recommend clarifying and rethinking “inclusion/exclusion criteria” by including anomalous data (e.g., outliers) in the analysis or considering the potential stratification of these data on the population’s responses to drug treatments.

Denayer et al. (2014) proposed introducing “clinical trial features” in animal research. They suggest, in consonance with Stewart et al. (2015), that assessing and reporting “negative” effects (pain, discomfort, dyskinesia, and other side effects) in preclinical research can improve the rate with which potential candidates are discarded before they progress in the pipeline. They also advocate adding predictive biomarkers for treatment responsiveness, such as pharmacogenomic data or peripheral biomarkers, as classifiers in the screening. Finally, they suggest that “reverse translation” is as important as other strategies to refine the model, as biomarker and endophenotype research in patients can inform further iterations of the model building and evaluation processes. Notice that these recommendations point to a feedback between external validity and predictive validity.

A final recommendation regards not the alteration or refinement of animal models but the addition of “nontraditional” stages in clinical trials by testing drugs in an experimental setting in patients. For example, startle reactivity, carbon dioxide sensitivity, and fear generalization have been shown to be altered in anxiety and trauma and stress-related disorders and can be used, in addition to classical tests, to study drug and/or gene effects in rodents (Hoffman 2016). Importantly, they can be used in human patients to test drug effects (Hoffman 2016). Thus, drug candidates that normalize the activity of these “back-translated” variables in animal models would be tested in human subjects using analogous test paradigms in addition to the clinical settings.

## Hypothesis-Free Model Building?

The focus on construct validity, with a strong theoretical basis, represents an important epistemological contribution, but does not necessarily cover everything that the scientists that use models and tests do. High-throughput techniques in neuroscience and biomedical research have produced a plethora of genomic and proteomic data which were not driven by a specific hypothesis and are rather exploratory in nature. These “Big Data” approaches include genome-wide association studies in animals and humans, microarray and RNA-Seq studies in animals, and other next-generation sequencing techniques. These strategies analyze thousands of genes or transcripts at the same time, in a “shotgun” approach to attempt to find polymorphisms that are associated with a disorder or genes that are up- or down-regulated after a given treatment or experimental manipulation. As a result, many potential targets which were not predicted by theoretical accounts appear.

In spite of the excitement that these studies generate, the pathophysiology of mental disorders is unlikely to be related to a mutation in one single gene, but rather to the effects in complex biological pathways which involve multiple interacting gene products (Kas et al. 2011). As a result, mechanistic and translational approaches to link the hits obtained using these high-throughput genomic/transcriptomic approaches and genome-wide association studies with relevant endpoints are necessary, even when the candidates were generated with these hypotheses-free approaches. Tactical approaches include the integration of multiple datasets from human and animal studies to identify converging evidence for the role of a given gene or pathway in that disorder (Kas et al. 2011).

While high-throughput genomic/transcriptomic approaches and genome-wide association strategies can certainly increase throughput, they are not without problems. While genetic validity is starting to figure as an important aspect of model building, using it as a starting point to develop a model does not preclude other aspects – including knowledge about species differences and context-specificity of behavioral strategies

that are used in a given test (Kas et al. 2009). While using an endophenotype can increase external and face validity because these units are more easily translatable between humans and non-human animals, the choice of a behavioral endophenotype is still subject to other aspects of construct validity, especially homological validity, as well as aspects of face and predictive validity. For example, it is not clear whether the elevated plus-maze is an adequate test for panic attacks, although it can more properly model the hyperanxious aspect of panic disorder. In that sense, prioritizing genetic validity as a starting point is a useful strategy but should be approached carefully in order not to fetishize the gene and forget other aspects of behavioral modeling.

One important limitation of these approaches is that starting from the gene(s) instead of the disorder often creates the need for exploratory research on a plethora of models. This difficulty has already been established in relation to the needs imposed by phenotyping research in genetically engineered mice: “This vast murine factory line (...) is demanding ever-faster analysis. And the answers are sought now, ideally in the form of easily set-up, easy-to-follow, standardized protocols with high test-validity and secure intra- and inter-laboratory reliability” (Crabbe and Morris 2004, p. 1175). The authors exemplify, with the water maze, a task that is used to assess spatial memory. Pressures toward standardization and automation of data collection exist and are justified by the need to increase throughput; however, variations of the task allow for the analysis of different aspects of spatial learning and memory, and some of these variations are labor-intensive and preclude a high number of replications. Again, whether a standardized, automated, high-throughput version of the task is ideal depends on its use.

This use of automated tests is sometimes lauded as an advantage; however, besides risking missing important variables, “the suggestion that automation is *per se* a good thing seems to be driven by the belief that automatically recorded data escape the influence of the experimenter. There are scarce data to support this idea” (Crabbe and Morris 2004, p. 1177). The important factor here should not be throughput, but the

appropriate interpretation of behavioral data “that is crucial to their validity” (Crabbe and Morris 2004, p. 1177).

In addition, “hypothesis-free” approaches have increased after the application of computational power to quickly solve multivariate statistical analyses, often in an exploratory fashion. Computerized tracking also allows for the decomposition of animal movement in terms of linear and angular velocity, turning frequency, formation of “homebases,” etc. As a result, the number of endpoints derived from a single animal increased dramatically, and some authors exploit that to produce multivariate analyses. For example, Cachat et al. (2011) exploited the three-dimensional character of fish movement and analyzed zebrafish swimming in a novel environment. The combination of manual and automated decomposition of swimming patterns produced 15 endpoints; these were evaluated after “anxiogenic” (repeated morphine withdrawal, alarm pheromone exposure, caffeine, belonging to a highly anxious phenotype) or “anxiolytic” (chronic ethanol, chronic fluoxetine, chronic morphine, acute nicotine) treatments, and the results assessed with hierarchical clustering analysis. The authors revealed that all anxiogenic treatments cluster together, while all anxiolytic treatments cluster together, based on their behavioral effects. Moreover, they also revealed two main behavioral clusters. This exploratory analysis, however, was not followed by confirmatory techniques and therefore should not be interpreted as revealing the underlying structure of zebrafish responses to novelty; moreover, the hypothesis-free character of the approach makes it difficult to understand specifically what each cluster or sub-cluster means in behavioral terms.

## Conclusion

Animal models are used to gain insight into studying brain-behavior relations under controlled conditions and to enable predictions about these relations in humans and/or a species other than the one studied or in the same species under conditions different from those under which the study was performed (van der Staay 2006). Animal

models need to be thoroughly developed and validated, keeping in mind the intended use of the model. The purposes of the model determine the set of validation criteria that it must fulfill. Although a “classical” set of criteria has been proposed by Willner (Willner 1984, 1986, 1991), new approaches have suggested extended sets of validation criteria (Belzung and Lemoine 2011; Maximino et al. 2010; McOmish et al. 2014; van der Staay et al. 2009). These criteria may also be applied for selecting an (established) animal model for neurobehavioral research.

## Introduction

In 2016, the Center for Disease Control and Prevention estimated that about 1 in 68 children in the United States have been diagnosed with autism spectrum disorder (ASD), corresponding to approximately one million individuals under the age of 21. The prevalence of ASDs increased sharply since the 1990s, though it is unclear whether this increase can be fully explained by to a true increase in incidence, as opposed to greater diagnosis or broader diagnostic standards. One of the current criteria for diagnosis of ASDs is that the symptoms must compromise normal daily function, either in terms of occupation and school, or in the maintenance of social relationships. As such, ASDs have substantial social and financial costs, costing an estimate of \$250–300 billion annually in the United States.

Effective pharmacological treatments for ASDs have remained elusive. Pharmacological interventions are used to treat comorbid symptoms of autism, such as anxiety and attentional deficits, but there are no currently approved drugs that will treat the core symptoms. One of the reasons for this failure is the lack of good animal models for the disease. Animal models of disease are crucial to drug discovery and development, as well as for a better understanding of the molecular, cellular, and network changes underlying the disease. To date, some animal models have been used to shed light on the neurobiological etiology of ASDs, or on the neurobiology of social behavior more generally, whereas others appear to capture crucial behavioral similarities and show promise for future ASD research.

True animal models of any disorder are defined by formal criteria, typically face, construct, and predictive validity. To achieve face validity, the animal model must have behavioral or biological markers associated with the disease. Examples of altered biological markers include disruptions in molecular pathways, neuronal wiring or computation, or anatomy. To achieve construct (or etiological) validity, the method used to recreate the disorder in an animal model must resemble genetic, developmental, and/or environmental causes of the disorder. That is, the etiology, or biological cause, of the disease is the same in

both the model and the afflicted individuals. Finally, the achievement of predictive validity signifies that the animal model responds to clinical interventions, such as pharmacological agents, in a manner that recapitulates the response of individuals with the disease.

Construction of ASD animal models that achieve all three of these criteria will be challenging, though incremental progress is being made. There is no known biological marker universal for all cases of ASD, so achieving biological face validity in an animal model is impossible. However, there are established animal models with behavioral face validity that are characterized by distinctive neurobiological abnormalities (e.g., synaptic dysfunction), which lead to the converse challenge of determining whether in individuals with ASD have similar deficits. Challenges also exist for construct validity: Though it is known that ASDs have a genetic component, genetic predispositions typically have small effects, and many different genetic mutations can be attributed to the disorder. There are also several possible candidates for environmental causes of autism, such as prenatal stress or infection, advanced parental age, or exposure to air pollution, but none of these has been unambiguously confirmed. Similar to these difficulties in face and construct validity, predictive validity of ASD in an animal model is currently difficult to achieve, as there are no available drugs that improve ASDs core symptoms.

Thus, crucial to any animal model of ASD is the achievement of face validity in the behavioral sense. This, too, poses a unique set of challenges, because ASD is extremely heterogeneous. Two individuals, both diagnosed with ASDs, could have completely different symptoms, with no overlap except that they broadly involve social deficits and repetitive behavior. Moreover, interpretation of ASD-like behaviors in nonhuman animals depends on the species-typical expression of those behaviors. For example, rodents rely heavily on tactile and olfactory information, whereas primates are heavily visual; and different species, even those that are closely related evolutionarily (e.g., prairie voles and montane voles), may exhibit vastly different social behaviors.

## ASD: An Overview

To meet the diagnostic criteria for autism according to the DSM-V, individuals must show both deficits in social communication and restricted and repetitive behavior. Deficits in social communication can present as an inability to abide by the unwritten rules that guide typical human social behavior. For example, we expect language to be more formal when addressing an authority figure, such as a teacher, than when addressing a friend during casual conversation. Voice volume modulation is expected according to context, such as in a library. Often individuals with ASDs have trouble interpreting tone of voice, body language, or facial expressions when communicating. They may have trouble understanding metaphors, figures of speech, or sarcasm, or have difficulty taking turns during conversation or indicating interest and social engagement during conversation using nonverbal cues. Individuals with ASD also fail to initiate joint attention, in which they draw another party's attention to an object or event of interest. Social deficits may or may not be accompanied by active avoidance of social interaction. Avoidance of social interaction in ASD can result from disinterest or anxiety, but some people with ASD display a so-called "active-but-odd" phenotype, in which atypical social communication accompanies strong pro-social behavior. Regardless, the typical individual with ASD has difficulty initiating and maintaining relationships. In extreme cases of autism, spoken language and communicative facial expressions may be altogether absent. For any of these symptoms, the onset occurs during childhood.

The second diagnostic criterion is the presence of repetitive behaviors and/or restricted interests typically found in autism. These can be manifested as repetitive motor behaviors (e.g., hand flapping), speech behaviors (e.g., echolalia, or repeating overheard words), or repetitive object behaviors (e.g., lining up or flipping toys). Individuals with ASDs often have rigid, inflexible behavior, insisting on sameness or rituals, and have trouble with transitions. ASD diagnosis can

also include restricted interests, highly focused and intense interests for particular topics or objects, such as trains or baseball statistics. Sensory sensitivity or under-reactivity can also be a diagnostic symptom of ASD, such as adverse reactions to sounds or light, excessive smelling or touching of objects, or indifference to pain or extreme temperatures.

For a diagnosis of ASD, these two major classes of symptoms are required to have arisen during childhood, and must cause significant impairment in everyday functioning, such as interference in occupation, school, or social relationships. ASD may or may not be accompanied by intellectual disabilities (previously termed “mental retardation”).

The diagnosis for ASDs thus allows for substantial heterogeneity in both severity and in presentation. An individual with ASDs may have extreme intellectual disability, or s/he may be a savant, with remarkable capacity for memory or knowledge. S/he may be unable to speak or otherwise communicate, or s/he may be typical, or even eloquent, in speech but “socially awkward.” Some individuals learn strategies for coping with their diagnosis, such that they learn to mask their symptoms as they get older. Others are severely debilitated, and require resource-intensive services throughout their lives.

This heterogeneity in those clinically diagnosed with ASDs parallels the heterogeneity of subclinical presentations of these symptoms among the typical population. For example, it is not uncommon for TD children typically to display repetitive or ritualistic behavior. Some adults are passionate, almost single minded, about their hobby interests, such as model trains or bird watching. Many typical adults have difficulty perceiving the nuances of conversation or body language. Subclinical, “autistic-like” traits in TD individuals have been termed “endophenotypes,” and are overrepresented among close relations of individuals with ASD. The clinical term “autism spectrum” refers to the broad spectrum of symptomatic severity present in ASDs, and may in fact be part of a larger spectrum of behavioral variance present in the typical population.

## Animal Models of Repetitive Behaviors

Repetitive behaviors in animals are enhanced by captivity. Lab rodents and non-human primates (NHPs) as well as a plethora of zoo-kept species, are known to move in stereotypic patterns. Incessant pacing, flipping, bar-biting, auto-grooming (self-grooming), and self-injurious behavior have all been described, though there is substantial variation across individuals. This behavior is presumably caused by anxiety and “frustration” at the inability to express species-typical behaviors such as foraging, allogrooming, and territory patrol, and can often be alleviated by environmental enrichment. Similarly, repetitive behaviors in ASD appear to be a coping behavior, and ASD individuals with high levels of repetitive behaviors have lower cortisol levels than those with low levels (Gabriels et al. 2013). Antipsychotics such as aripiprazole and risperidone decrease repetitive movement in ASD individuals, an effect paralleled in some stereotypic animals.

Commonly assessed repetitive behaviors in rodent and nonhuman primate models of autism include stereotypic motor movements, pacing, and auto-grooming (Silverman et al. 2010). Another assessment of repetitive behavior in rodents is a marble burying assay. Defensive burying in rodents, in which they use their forepaws and heads to displace bedding in order to cover noxious objects, is part of their normal repertoire of behaviors. Small, discrete aversive objects, including electrified prods, noxious food objects, startling stimuli, and predators or predator odor, are all known to elicit this behavior, though mice will also attempt to bury larger threats, such as live scorpions. Rodents will also bury marbles, despite the fact that marbles are not aversive to mice based on avoidance assays. Marble burying behavior is also not correlated with performance on assays of anxiety, suggesting that repeated displays of this behavior reflects perseveration, rather than anxiety (Thomas et al. 2009).

Behavioral rigidity and resistance to change are also hallmarks of ASD, and there are established protocols for measuring resistance to change in animals. Most prominent of these are the reversal

learning paradigms, in which the animal must inhibit previously rewarded behavior. For example, a rat or mouse will be placed in a t-shaped maze in which either the left or right arm is baited with a food reward while the other arm remains empty. Once the rat learns to travel down the arm containing the reward, the reward contingency changes, such that the baited and unbaited arms are swapped. The rat learns to suppress the previously rewarded behavior in favor of the rewarded arm under these new circumstances, and the rate of this learning, or the number of errors, serves as an index for behavioral flexibility. The evolution of reversal learning in animals was likely driven by neural adaptations for foraging in fluctuating environments. Foraging animals use their spatial memory and reward history to return to locations in which they previously found food, but, to avoid forgone foraging opportunities and unnecessary energy expenditure, there would be strong selective pressure to evolve the ability to override previous foraging patterns once the food in a patch was gone.

In humans, rats, and rhesus macaques, orbitofrontal cortex and amygdala lesions increase perseveration of the incorrect choice after reward reversal, suggesting a crucial role for these structures in behavioral flexibility (Rudebeck and Murray 2008). Some researchers propose that a lack of self-control and inappropriate behavioral updating are fundamental cognitive deficits in ASD, stemming from abnormal development of an OFC-amygdala neural circuit. In some subtypes of ASD, deficits in the ability to flexibly update behavior may underlie both an insistence on sameness as well as an avoidance of social interaction, which tends to demand cognitive flexibility. Notably, however, though deficits in cognitive flexibility are inarguably present in day-to-day activities, the performance of ASD individuals on laboratory measures of cognitive flexibility, including reversal learning tasks, is mixed, leading some to suggest that better tasks in humans are required in order to isolate the cognitive constructs underlying inflexible behavior. This finding also reduces the face validity of reversal learning task deficits in animal models.

## Rodent Models of Social Dysfunction

Summarized below are the main assays used to measure social phenotypes in rodents:

- **Reciprocal social interactions** – Decreased interactions, including nose-to-nose sniffing, anogenital sniffing, play behavior in juveniles, and close physical contact between two or more mice may indicate lower sociality in rodent models.
- **Social approach task** – Mice are placed in the central chamber of a three-chambered apparatus, with the peripheral chambers containing a novel mouse or a novel object. The time spent in the chamber containing the mouse is a measure of social approach.
- **Social preference task** – Mice are placed in an apparatus identical to that used in the social approach task, but the peripheral chambers contain a novel mouse or a familiar mouse. Typically mice spend more time in the chamber containing the novel mouse.
- **Partition test** – Mice are placed in a cage divided in half by a perforated plastic partition, with a social partner placed on the opposite side. Social interest is measured as the amount of time spent at the partition.
- **Social transmission of food preference** – Rats will typically develop food preferences for a particular flavor (e.g., cocoa or cinnamon), after interacting with a social partner that has consumed that flavor. Rats sniff the face and whiskers of the demonstrator rat and the smell of the consumed flavor combined with volatile chemicals in the demonstrator's breath, will induce a bias toward that flavor in the target rat when subsequently presented with a flavor choice task.

## Animal Models of Vocal Communication

Most mammalian vocalizations are produced instinctively, relatively unshaped by social learning. This is demonstrated in part by experiments with squirrel monkeys and rhesus macaques, which, when cross fostered, deafened, or reared

in isolation, still have normal vocal development. Many mammalian vocalizations, including those of rats and rhesus macaques, appear to be associated with different emotional states. Rodents emit various types of ultrasonic vocalizations (USVs), and aberrations or decreases in these vocalizations have been demonstrated in some genetic models of ASD. Newborn pups will emit a 40-kHz USV when their temperature falls beneath a certain threshold, typically after they've wandered away from the nest. Their vocalizations trigger retrieval behavior in the mother rat. Juvenile rats will also emit "rat laughter" during play bouts with other individuals or when being "tickled" by a human investigator. This type of vocalization is clearly associated with positive affect, as rats will actively approach and pursue an experimenter's hand after a tickling bout, and tickling can be used as positive reinforcement to drive instrumental learning. Adult rats will also emit 22 kHz alarm cries in the context of inescapable aversive stimuli, including during male-male aggression and social defeat. Despite the association of these various USVs with different emotional states, it is unclear what communicative function, if any, these vocalizations serve.

Adult mouse USVs are emitted during social interaction, especially mating, but do not seem to reflect the affective state of the animal. USVs of adult mice consist of various syllables with distinctive acoustic properties that are emitted in nonrandom patterns, similar to birdsong, though the function of these vocalizations is unknown.

In contrast to the innate vocalizations of rodents and rhesus macaques, birdsong is a model of human language in that it emerges during a critical period early in development, requires social learning, and is reliant on specialized brain structures (Panaitof 2012). Juvenile songbirds will learn the song to which they are exposed, usually their father's song, after hatching. During this critical period of song learning, young songbirds "babble," stringing together "nonsense syllables" that eventually form into a coherent song. Once the critical period of learning closes, the song is "crystallized," and learning is severely limited. Interestingly, at least two autism susceptibility genes have been found to be

associated with aspects of song learning in birds. One of these, contactin-associated proteinlike 2 (*CNTNAP2*), encodes a neural cell adhesion molecule that serves as a target of the language and birdsong-related transcription factor FOXP2. *CNTNAP2* is related to brain sexual dimorphism in the songbird and has transcription specific to birdsong neural circuitry (Panaitof 2012). A second gene, *FMR1*, has dynamic transcription, leading to an increase in production during the beginning of the sensorimotor practice stage of song learning. *FMR1* is the cause of fragile X syndrome, which has a high comorbidity with ASD.

A few other species, like baboons, vervets, and prairie dogs, have "referential" vocalizations, in which various vocalizations map onto different types of predators. Vervets respond appropriately to the different alarm calls: in playback experiments, they look up into the sky and run into the bushes in response to "hawk" calls, and go up into the trees in response to "leopard" calls. Young vervets are more likely to give inappropriate calls, suggesting that the function, if not the structure, of these vocalizations require learning.

Marmosets, small, new-world primates that live in family groups, appear to have "conversations," in which they take turns vocalizing. As in humans, younger animals are more likely to interrupt conversations than older animals. Human vocal turn taking develops extremely early, typically between 4 and 7 months of age, before the infant has full speech development. Marmoset turn taking increases at the equivalent point in development (Takahashi et al. 2016). Conversational turn taking is often difficult for individuals with ASD. Better characterization of marmoset social behavior, combined with the potential for genetic manipulation in this species, may make this animal a more heavily used model of ASDs in the future.

## Genetic Models of ASD in Mice

Familial and twin studies of ASD have established beyond doubt that ASDs are influenced by genetics, and many mutations that are risk factors for

ASDs have been identified (Abrahams and Geschwind 2008). However, this genetic contribution is not straightforward: There is no single gene known to be associated with all cases of ASD; thus, ASDs are as genetically heterogeneous as they are behaviorally heterogeneous. Scientists have identified genetic mutations in about 20% of ASD cases, but each known mutation individually accounts for only 1% or less of ASD cases. With the advent of genomic manipulation, knock-in, knock-out, and transgenic mouse models relevant to ASD have been developed, allowing for the exploration of the behavior and etiology associated with ASD risk genes. As with nonpsychiatric diseases, mice can be engineered to replicate human mutations, so as to facilitate the study of the biological and neural changes that result from this genetic change. These genetic manipulations are typically performed on mice that are all of the same background, i.e., are essentially clones of one another, in order to avoid confounds that would arise from polymorphisms elsewhere in the genome.

The study of many ASD-associated genetic mutations in mice has begun to shed light on the common pathways and mechanisms affected by disparate mutations. Many genes are implicated in synaptic changes, such as *SHANK2*, *SHANK3*, *NLGN*, and *NRXN*, which code for proteins that govern synaptic adhesion. Other ASD-associated genes, e.g., *GRIN2B*, influence excitatory neurotransmission, and glutamatergic signaling, inhibitory signaling, and the balance of the two, may be another mechanism giving rise to altered connectivity and ASD-like deficits.

Some diseases that result from known genetic deficits, such as Fragile X Syndrome and Rett Syndrome, are highly comorbid with ASD. In some of these syndromes, the molecular pathways are relatively well defined, for example, the rapamycin (mTOR) signaling pathway in the case of tuberous sclerosis (TSC), and synaptic dysfunction in Rett Syndrome and Fragile X. TSC provides a good example of how mice containing a mutation for a syndrome known to be associated with ASD can shed light on the etiology of the disease. Tsc proteins regulate cell growth and axonal, dendritic, and synaptic

development and function. Individuals with TSC have the classical cortical tubers throughout the brain, as well as disorganized white matter tracts and aberrant synapse formation (Jeste and Geschwind 2014). Knockout mice with damage to the *TSC* genes have shown various cognitive deficits, including impairments in social interaction and repetitive behaviors and vocalization (Tsai et al. 2012). These mouse models provided the means by which to examine the larger molecular pathway influenced by *TSC* mutations, as well as the identification of a class of molecules that regulate the *TSC*-related pathways, mTOR inhibitors. mTOR inhibitors were found to rescue the cognitive and social impairments in knockout mice, and are now in clinical trials for patients with TSC.

## Environmental Models of ASD

Unlike syndromic cases of ASD, such as TSC, ASD is in many cases likely to result from an interaction between a genetic susceptibility and some environmental feature. The identification of environmental causes of ASD is still very much uncertain at the time of writing, but there is substantial evidence that most environmental insults leading to ASD occur prenatally. As a developmental disease, exposure to an environmental risk factor may have to overlap with a particular developmental stage, such as neural tube closure, in order to result in ASD. Potential environmental contributors to ASD include prenatal maternal stress, infection, and exposure to traffic-associated air pollutants.

### Valproic Acid

A useful environmental animal model of ASD is prenatal sodium valproate (VPA) exposure. VPA is an anti-epileptic and a mood stabilizer. If taken while pregnant, it triples the risk of having a child with ASD (Kazdoba et al. 2016). In mice and rats, in utero exposure to VPA causes altered social behavior in many assays of social behavior in mice and rats including decreased juvenile play and social exploration of a stranger (Kazdoba et al. 2016). Maternal VPA also induces repetitive

behaviors in the offspring, including increased motor behavior in the cage, stereotyped behavior, self-grooming, perseveration on a y-maze, increased marble burying, and decreased ultrasonic vocalizations. Interestingly, exposure to valproic acid transiently increases the transcription of Pax-6, a transcription factor implicated in the differentiation of glutamatergic cells, leading to increased expression of glutamatergic proteins. This observation is consistent with the ASD-like phenotypes observed during optogenetic interruptions in excitation/inhibition balance in mice (Yizhar et al. 2011), as well as with ASD risk genes associated with glutamatergic signaling (e.g., GRIN2B).

### Maternal Immune Activation

Epidemiological studies have linked maternal infections during pregnancy and ASD: Maternal infections of rodents induces ASD-related behavior in the offspring, including altered USV emission and impaired nest-seeking in pups, reduced social exploration in a three-chamber test, reduced social USV emission in adults, and a variety of repetitive behaviors, including self-grooming and marble burying. The effect of maternal infection seems to depend on the time of infection, with infections around the time of neural tube closing having the most reliable effects. Interestingly, the deficits seem not to be caused by the infection *per se*, but to the immune response to the infection. Introduction of nonpathogenic molecules such as poly-inosine:cytosine and lipopolysaccharide, which are nonpathogenic but evoke an immune response, are also effective in recreating ASD phenotypes in mice (Servadio et al. 2015).

### Neural Network Substrates of Social Behavior

Human interest in visual social information is adaptive, and the compromise of this social motivation and attention, as occurs in ASDs, is pathological. The kinds of adaptive social behaviors expressed by each species vary. In rodent models of ASD, rats and mice are assessed as having decreased social interest by exhibiting decreased reciprocal social interaction, such as sniffing and

following; lower exploration of another rat or mouse in a choice task; and/or decreased social play. In contrast, NHPs are primarily visual, rather than olfactory, and are capable of performing a large number of trials in highly controlled, visually guided choice tasks. A disproportionately large area of the primate brain performs visual computations, with over 30 dedicated regions devoted to visual processing. Many of these regions are specialized to process social information. Accordingly, primates also have specializations to send social information, including elaborate facial muscle specializations in the eyes, brow, cheeks, and lips with which to produce a wide range of facial expressions.

Based on patterns of cellular distribution and morphology, NHPs have subregions of frontal cortex that are orthologous to those in humans which are either absent or undifferentiated in rodents. The so-called “social brain” in humans is comprised of a network of areas highlighting the temporoparietal junction, anterior cingulate, fusiform face area, ventromedial prefrontal cortex, orbitofrontal cortex, and amygdala (Tremblay et al. 2017; Watson and Platt 2012a). Importantly, these regions have been found to be altered in fMRI studies of individuals of autism, as well as integral to social cognition in TD humans.

The face is a powerful social cue, and individuals with ASD fail to utilize this cue to its full extent. Both rhesus macaques and humans have face-selective regions required for face recognition in the temporal cortex, as identified by fMRI, and recording from rhesus macaques in these patches reveals that nearly 100% of the neurons in these regions are responsive to faces (Tsao et al. 2006). Individuals with ASD have deficits in their ability to remember and discriminate facial identities, and activate their amygdala and fusiform gyrus less than controls during facial emotion recognition tasks (Harms et al. 2010).

In particular, viewing others' eyes yields rich and dynamic social information. When presented with face images, TD individuals spend a disproportionate amount of time looking at the eye region. This is also true for NHPs including chimpanzees and rhesus macaques. In contrast, ASD

individuals avoid eye contact. Eye tracking studies show that individuals with ASD have fewer fixations in the eye regions; Infants who later develop ASDs exhibit declines in eye contact during 2–6 months of age; and performance of ASD individuals on the classic “reading emotion from the eyes” test, in which participants report the emotion being expressed based on images cropped to reveal only the eye regions, is compromised relative to TD individuals. This lack of a bias to look at the face and eyes deprives individuals of ASD of a rich source of social information.

Typically, TD individuals reflexively orient toward social information and attach value to this social information. That is, they find social information rewarding. One theory of autism is that social motivation deficits are at the root of social impairment (Chevallier et al. 2012). If children are not motivated to preferentially attend to social stimuli early in development, as are TD children, then they will not develop the expertise necessary for subsequent elaborations and refinement of various social skills (Chevallier et al. 2012). The social motivation network includes the orbitofrontal cortex (OFC), ventromedial prefrontal cortex (VMPC), striatum, and amygdala, structures which interact to compute the value of environmental stimuli and guide attention accordingly (Chevallier et al. 2012). Functional differences in this network correlate with individual difference in social motivation (Chevallier et al. 2012). Evidence for decreased social motivation in ASD include the core diagnostic criteria of early (<1 year) decreased orienting toward one’s name, social aloofness, and decreased eye contact, as well as eye tracking results showing fewer fixations on social vs. nonsocial objects when viewing images and movies. Moreover, ASD individuals have diminished preference and attention toward social sounds, including speech, vs. nonsocial sounds (Chevallier et al. 2012).

Electrophysiological studies in rhesus macaques shed some light on the role of cortical neurons in the processing of socially motivated behavior. Single cells in the OFC were recorded while monkeys performed a task designed to measure the NHP’s preference for various social

images and juice rewards. This revealed that neurons in the orbitofrontal cortex, which had previously been shown to encode subjective preference for various rewards, consists of spatially intercalated sets of individual neurons that respond preferentially to the receipt of social rewards or juice rewards (Watson and Platt 2012a). Recordings from other areas using the same behavioral paradigm exemplified the diversity of neural computation across the brain. In the lateral intraparietal region, neurons signaled the value of both social and juice rewards only when the assessment influenced the animal’s visual orienting decisions, thus establishing this region’s importance for motivated visual attention. Finally, neurons in the striatum signaled information about the type of reward, social vs. juice, without encoding the animal’s preferences for these rewards (Klein and Platt 2013).

Other experiments on NHPs that require the animals to make decisions that influence both itself and another animal are similarly revealing. Importantly, rhesus macaques were shown to derive reinforcement from the reinforcement of another animal, a phenomenon termed “vicarious reinforcement.” This is a type of emotional contagion, thought to be a precursor to empathy. Probing the frontal cortex in conjunction with the vicarious reinforcement task revealed that different subregions encoded different aspects of the task, with OFC encoding the amount of reward being delivered to one’s self, but not to another monkey, and with neurons in the anterior cingulate sulcus encoding forgone rewards, delivered to another monkey or to no-one, but not to one’s self. On the other hand, neurons in the anterior cingulate gyrus encoded rewards delivered to one’s self, to another monkey, or to both monkeys simultaneously, suggesting a shared role in vicarious and direct reinforcement (Chang et al. 2013).

## Multisensory Integration and ASD

Sensory processing dysfunction is common across the ASD spectrum, with 95% of children with ASD reporting sensory hyper- or hypo-responsiveness. These manifest as deficits in

unimodal sensory processing, including in the auditory, visual, and tactile domains, as well as in multisensory integration, in which multiple modalities are recruited simultaneously. Integration of information across modalities is particularly important for speech perception. Binding together auditory and visual information in a noisy environment, for example, while participating in adult conversation at child's birthday party, confers substantial increases in speech comprehension. The addition of visual information to auditory information during speech perception is equivalent to increasing the volume of the auditory information by 15 db. Impairments in multimodal integration, even if they stem from relatively low level sensory deficits, can potentially disrupt higher order cognitive processing, particularly social processing. For example, relative to TD individuals, children with ASD have decreased temporal binding of audiovisual speech cues, and the extent of this binding deficit in ASD individuals is predicted by the acuity of temporal binding during low-level, non-speech audiovisual stimuli (flashes and beeps) (Stevenson et al. 2014).

Audiovisual binding is represented in single neurons, as evidenced by studies in the rhesus macaque. When rhesus monkeys are shown videos of other monkeys making vocalizations, responses in primary auditory cortex neurons are enhanced when the visual information co-occurs with the auditory information within a certain time window, around 70–100 ms. In contrast, longer time intervals between the onset of visual and auditory information (around 200–330) leads to suppression of neuronal firing in the primary auditory cortex (Ghazanfar et al. 2005). The neural enhancement of integration seems to be specific to social stimuli, as pairing the vocalization with a movie of a black disk mimicking the dynamics of the mouth movement did not generate the same neural enhancement that occurred when viewing a movie of a monkey face vocalizing. This study demonstrates that neurons in the auditory cortex are capable of recruiting visual information during vocalization representation, and suggests that low-level sensory processing difficulties are likely to interfere

with speech-related brain signals in ASD. Far from being a property unique to primary sensory cortex, however, multisensory integration is a feature seen throughout the cortex. Therefore, a cellular or network change that interferes with global multisensory integration in ASD could account for a wide variety of ASD features.

## Oxytocin, Social Behavior, and Autism

Oxytocin is a neuropeptide that orchestrates mammalian behavior related to reproduction, parental care, and social affiliation. It is produced in the hypothalamus and circulated both throughout the brain and, via the pituitary, released in the body. In the brain, oxytocin binds to nerve cells through specialized receptors. Animal models are crucial to understanding the mechanisms of OT on behavior, as central OT release can only be measured invasively. Oxytocin regulates the so-called “ $\gamma$ -aminobutyric acid (GABA) switch,” in which neurotransmitter GABA shifts from excitatory to inhibitory around the time of birth. Several studies have identified genetic variations within the oxytocin pathway that are associated with autism and autism-related endophenotypes. Oxytocin is also under investigation as a biomarker for autism, as oxytocin plasma levels seem to correlate with either autism or with social impairments more generally. Manipulation of oxytocin has positive effects in many rodent models of ASD, either by correcting social deficits, restoring peripheral oxytocin levels, or reinstating the GABA switch (Peñagarikano 2017). These animal studies are corroborated by human studies that relate intranasal delivery of OT to ASD individuals to positive effects on social behavior, as measured by recognition of affective speech, Reading the Mind through the Eyes test, social cooperation and social selectivity in an online ball playing game, and enhancing attention to the eyes and face of others (reviewed in Stavropoulos and Carver 2013). However, many of these studies have been acute, single dose studies of OT, and the effect of long-term dosing of OT on individuals with ASD is currently under investigation as of 2018.

Early studies of oxytocin in sheep demonstrated the importance of this molecule in establishing a bond between parent and offspring. Sheep mothers strongly and selectively bond to their own offspring and reject foster offspring. The identity of their offspring is mediated by olfactory cues shortly after birth, and central infusion of oxytocin in absence of parturition is sufficient to cause a hormonally primed ewe adopt a foster lamb (Keverne and Kendrick 1992). Peripheral OT levels in human parents are associated with stronger bonding, greater contact, and higher synchrony between parent and child (Feldman and Bakermans-Kranenburg 2017).

In addition to being crucial to the establishment of the parent-child pair bond, oxytocin and the closely related neuropeptide vasopressin are also known to facilitate pair bonds between mates. Prairie voles, which are monogamous, and montane voles, which are promiscuous, are closely related rodent species. When housing captive mated pairs, prairie voles huddle in close proximity with their partner, whereas montane voles typically sit in opposite corners of the cage, maximizing the distance between individuals. As with mother/offspring bonding in sheep, a female prairie vole's attachment to her mating partner is mediated by oxytocin. When oxytocin is infused into the central nervous systems of female prairie voles, it creates a partner preference for male voles even in the absence of mating. The partner preference does not occur when the oxytocin infusion is paired with the delivery of an antagonist blocking the oxytocin receptor.

OT also appears to play a role in human romantic relationships. OT levels are higher in individuals in new romantic relationships than in singles, and OT levels correspond to overall relationship satisfaction. However, OT levels do not unambiguously correspond to relationship bliss in all contexts. For example, OT has also been associated with relationship stress and anxiety. It is clear that OT influences human pair bonds, but the way in which it does so is complex and not completely understood.

NHPs offer an important model to study the delivery, mechanisms, and behavioral effects of exogenous oxytocin. In male marmosets, a new

world monkey that exhibits biparental care, intracerebroventricular infusion of oxytocin reduces the rate of refusal to share food in response to juvenile offspring begging (Saito and Nakamura 2011). Exogenous oxytocin also seems to facilitate pair bond formation in marmosets, as intranasal oxytocin administration increases huddling behavior with their social partners (Smith et al. 2010).

Because peripheral applications of oxytocin probably do not reach the CNS, most clinical trials of OT for ASD rely on intranasal administration of OT. Studies on rhesus macaques show that intranasal applications delivered via nasal spray or nebulizer both influence cerebral spinal fluid (CSF) OT levels, whereas only nebulizer OT delivery alters plasma OT levels. Knowledge of the physiological differences arising from differences in OT delivery methods will be crucial for the development of an OT-based ASD intervention.

When combined with visual decision making tasks, the application of OT allows researchers to precisely assess how increases in central oxytocin levels affect the attention and preferences of NHPs with respect to social stimuli. For example, intranasal OT influenced behavior in a task that allowed a monkey to choose between targets that would deliver juice rewards to either himself, to another monkey, or to no one (an empty beaker). When the choice is between another monkey and an empty beaker, monkeys show enhanced rates of choosing to deliver reward to the other monkey after OT administration, as well as increased attention toward the other monkey (Chang et al. 2012). On the other hand, when choosing between juice delivery to another monkey and one's self, OT delivery increases the number of selfish choices. Oxytocin has also been shown to influence rhesus performance on a social attention task. As in humans, oxytocin in rhesus macaques increases the amount of attention to faces and eyes (Ebitz et al. 2013). It also increases vigilance for dominant individuals, a threatening social stimulus, though it does not change attention toward nonthreatening social stimuli, such as subordinate individuals or reproductive images (Ebitz et al. 2013).

Rhesus macaques also provide the opportunity to study the relationship of early life experiences and OT variations or manipulations with ASD related behaviors. Peer reared macaques that have been deprived of maternal care have lower CSF OT levels, and these are associated with reduced pro-social behavior, increased aggression, and increased stereotypic behavior (Winslow et al. 2003). Performance of male infant macaques on a face recognition task predicts endogenous central OT levels, but not peripheral OT levels, up to 5 years after the assessment (Madrid et al. 2017). Oxytocin application enhances working memory and social gaze tracking in male, but not female, infant macaques (Simpson et al. 2017).

### Advantages and Disadvantages of Different Models

Different animal species have different costs and benefits as models of ASD. First and foremost, mouse models offer superb genetic malleability. However, genetic techniques currently under development may soon make it easier to produce genetic models of ASD in other species, including NHPs such as marmosets and rhesus macaques. Other advantages of mice include their short developmental time courses, allowing for high throughput; their smaller size and less expensive housing and husbandry demands; and the relatively established assays for general health and intact sensory abilities, which are a prerequisite for testing downstream cognitive faculties. Many researchers argue that rodents have the key brain structures relevant to ASDs, including the amygdala and hippocampus, cerebellum, and basal ganglia. Finally, mice and rats, along with rhesus macaques have a long history of use as a biological model, resulting in a rich literature of the molecular and neurobiological substrates of their behavior and physiology. This literature is not as deep for less commonly used species, including birds and voles.

NHPs as animal models of ASDs are less practical than mice, but offer some important benefits (Watson and Platt 2012b). As noted above, rhesus

macaques can perform visual decision making tasks that allow researchers to rigorously determine the effects of social stimuli on the behavior of the animals. Importantly, these tasks can often be designed to be similar or identical to those employed in humans, offering unparalleled face validity. Many of these tasks rely heavily on the highly developed visual sense of primates, which is in contrast to the emphasis on olfaction found in most other mammals. NHPs display similarities to human social behaviors that most rodents lack, such as group living, dominance hierarchies, alliance and coalition formation, consortships, and intergroup warfare. Humans and NHPs share neural specializations common to the primate order, such as an expanded frontal cortex, that may be critical to the etiology of ASD. Rodents, lacking this fine differentiation of frontal cortex, may provide only part of the answer.

### Conclusion

Animal models reflect many ASD-related phenotypes relating to both social and repetitive behaviors. Genetic and environmental alterations in mice have revealed important hypotheses about the neurobiological underpinnings of ASD, such as excitation/inhibition balance and alterations in neural connectivity and synaptic structure. At the same time, studies in the rhesus macaque continue to yield a rich literature about the primate-specific neural circuits in the temporal and frontal lobes that are affected in ASD. Other species-specific cognitive specializations provide excellent models for domains of affected behavior in ASD, such as songbirds for language development, and marmosets for parenting and vocal turn-taking behaviors. Because ASD is heterogeneous in presentation and etiology, it will take many different animal models to understand, and ultimately treat, the disorder.

## Introduction

Historically, there has been much debate surrounding whether animals can be used to study psychopathological syndromes that occur in humans. It has been argued that many mental illnesses are uniquely human and that it is not possible to study mental disorders in nonhumans due to their lack of ability to communicate through speech. However, it is now widely accepted that not only do animals experience various psychopathological syndromes similar to those observed in humans, but they can also be used as a model to study mental disorders in humans. For the past few decades, researchers have been able to use animal models to study disorders such as anxiety, depression, schizophrenia, and OCD. Analysis of animal behavior, neural circuitry, brain activity, and response to pharmacological compounds provides valuable information on these disorders, which may shed light on the disorder in humans. Given the subjective nature of many important symptoms of these disorders, however, it has proven very difficult to model human psychiatric disorders in animals. Perhaps the first person to study emotion in animals was Darwin, although his studies were limited solely to the expression of normal emotions (Walker 1991). Pavlov was the first scientist to propose that animals can be used to study psychiatric disorders that occur in humans. Pavlov's conditioning studies that demonstrated that dogs could learn to use a neutral cue to predict a biologically relevant event would eventually shed light on the development of PTSD and anxiety disorders in animals and humans (VanElzakker et al. 2014). Research on animal models of psychopathology increased drastically during the early-to-mid-twentieth century, and much of the work was concerned with schizophrenia and neurosis.

Much of the controversy surrounding the use of animals to model psychopathology in humans stems from the difficulty in proving these models as valid, due to the reliance on the *diagnostic and statistical manual of mental disorders* (DSM)/*International Classification of Diseases* (ICD) as a conceptual framework to diagnose

psychiatric disorders. Many of the symptoms used to diagnose psychiatric disorders in humans (e.g., delusions, hallucinations, thought patterns, obsessions) cannot be reliably ascertained in animals. Certain behavioral patterns can be observed, which may allow scientists to approximate these symptoms in animals, but this process is by no means exact. Many scientists have discussed the challenges surrounding the construction of valid animal models, and the majority of them have utilized a hierarchical list of criteria introduced by Paul Willner to assess the validity of animal models of depression (Kaffman and Krystal 2012). These criteria include face validity, predictive validity, and construct validity (Willner 1984). Face validity refers to the model's ability to demonstrate specific behavioral, biochemical, and anatomical features of the human disorder. Predictive validity refers to the ability of the model to behave similarly to humans in response to different clinical interventions. Construct validity refers to the model's ability to demonstrate some characteristics of the underlying pathophysiology. Perhaps the biggest challenge for establishing animal models with construct and predictive validities is the absence of reliable genetic markers or pathognomonic pathological lesions (Nestler and Hyman 2010).

Scientists have been able to generate animal models of psychiatric disorders using a variety of methods: genetic engineering, selective breeding, brain lesions, environmental manipulations, optogenetic manipulations, and administration of pharmacological compounds. When developing these disease models, particular biochemical pathways, proteins, or neural circuits may be altered, which presents a challenge to scientists in determining whether the disease model is simply a phenocopy, or whether it truly models a human disorder with useful implications for understanding the pathophysiology and developing treatments. The ultimate goal of an animal model should be to demonstrate similarities with humans in terms of the symptoms, etiology, therapy, and prevention of the disease. Often, it is not possible for the animal model to demonstrate similarities in each of these criteria, so the development of mini-models is a popular method to study a particular

aspect of a disorder (Book). Mini-models are behavioral phenomena studied in animals that may shed light on either the symptoms, etiology, therapy, or prevention of the disorder in humans. Mini-models usually do not account for all symptoms of a disorder, but may still prove useful in studying certain aspects of the disorder. The psychiatric disorders that have been most widely studied using animal models include depression, anxiety and related disorders, schizophrenia, and bipolar disorder.

### Animal Models of Depression

Although recent advances in technology have allowed for a deeper understanding of the disruption in neural circuitry, as well as the neuroendocrine and neurochemical disturbances underlying depression, none of these biomarkers have proven to be sufficient in diagnosing depression in humans nor in validating existing animal models (Krishnan and Nestler 2008). However, depression is often characterized by overstimulation of the hypothalamic-pituitary-adrenal (HPA) axis, and although this abnormality is not always observed in humans with diagnosed depression, it is useful in producing animal models of depression. In humans, the DSM is used to diagnose depression based on a cluster of highly variable symptoms, including irritability, guilt, suicidal thoughts, ruminations, and anhedonia. With the exception of homeostatic symptoms, anhedonia, and psychomotor behaviors, the majority of symptoms used to diagnose depression cannot be objectively measured in animals (Nestler and Hyman 2010). Because animal models cannot perfectly replicate human psychopathology, different models may prove more useful depending on the question being asked and the nature of the experiment (McKinney 1984). For example, scientists who are testing the clinical effects of a pharmacological compound, and scientists studying the behavioral and neurobiological components of depression, will likely use different models. In the case of testing the clinical effects of a new compound, the primary concern is the empirical validity of the model in predicting

the therapeutic efficacy of the drug, while the behavioral similarity of the animal model to humans becomes secondary.

Various methods are used to generate animal models of depression. It is known that stress and emotional losses are potent risk factors for depression, and different chronic stress paradigms have been utilized to produce a level of construct validity. One of the most common ways to administer chronic, unpredictable physical stress is to subject normal animals to repeated physical stressors over a period of weeks, or even months. These physical stressors may include electrical shocks, physical restraints, or extreme temperatures. Following periods of chronic physical stress, animals show anhedonia, which may be reversed by chronic administration of antidepressants (Willner 2005). Another way to model depression in animals is to subject them to chronic social defeat stress. When animals are subjected to repeated bouts of social subordination, they begin to display depressive symptoms such as anhedonia and social withdrawal, which may be reversed by chronic administration of antidepressants (Krishnan et al. 2007). Generating rodent models of depression through chronic social defeat stress may be advantageous to models generated through chronic physical stress. Chronic social defeat induces a metabolic syndrome in rodents which results in weight gain, as well as insulin and leptin resistance, which is consistent with homeostatic abnormalities seen in humans with depression (Chuang et al. 2010). Additionally, some rodents fail to develop symptoms of depression when exposed to chronic social defeat, which provides scientists for a model to study resilience to depression. Another model of depression that has shown a high amount of construct, face, and predictive validity is generated through early life stress. Rodents exposed to significant stressors early in their life, such as maternal separation, experience chronic neuroendocrine and behavioral abnormalities, some of which may be reduced through chronic administration of antidepressants (Meaney 2001). It has also been found that anhedonia can be induced in adult rodents which are socially isolated, and antidepressants can be effectively used to treat this effect (Wallace et al. 2009).

When analyzing the validity of different animal models of depression, it is very important to consider the means with which depressive symptoms are being induced. For example, the learned helplessness, forced swim, and tail suspension tests all involve exposing normal rodents to short-term stressors (Maier and Watkins 2005). This model may not provide useful information for translational studies, as depression in humans arises from a combination of underlying genetic vulnerability as well as exposure to chronic environmental stressors. Measuring certain depressive symptoms in rodents can be fairly straightforward. The two symptoms which are most commonly tested in order to measure the validity of an animal model of depression are anhedonia and homeostatic symptoms (Willner 2005). Anhedonia can be measured by observing the animal's interest in partaking in pleasure-inducing activities, such as engaging in social or sexual behaviors or showing a preference for a sucrose solution over plain water. However, with the sucrose preference test, there are a few issues to consider when designing the experiment. First, the concentration of sucrose should be taken into account, and if the concentration of sucrose is too high (>10%), rodents exposed to chronic stress may still prefer the sucrose solution over water. Also, there has been some concern over the use of sucrose as an alternative to water, as sucrose has a much higher caloric content and may be preferred by the rodents regardless of their exposure to stress. To address this issue, some researchers use saccharin as opposed to sucrose. While much progress has been made in the study of psychopathology and animal models of psychopathological syndromes, it is still far from an exact science, and there is still much progress to be made (Overstreet 2011).

## Animal Models of Anxiety

Fear and anxiety are emotions that have been evolutionarily selected for and which possess great adaptive value for organisms. Fear is an emotional response to a specific threat, while anxiety is an emotional response to a threat

that is unknown (Graeff and Guimarães 2012). Experiencing anxiety is normal and evolutionarily adaptive, but anxiety disorders can be quite pervasive and affect an individual's performance in everyday activities. As with animal models of all psychiatric disorders, animal models of anxiety do not replicate every aspect and symptom of anxiety disorder in humans. Rather, researchers attempt to generate a general state of anxiety in animals which may be related to anxiety disorder in humans (Lister 1990). In rodents, a state of anxiety may be produced by exposure to conflict situations generated by opposite motivational states which arise during approach-avoidance situations (Campos et al. 2013). For example, approach behaviors may be observed during conditioned responses in which a rodent is taught to seek or approach a certain object or location. It can also be observed when placing a rodent in a new environment, as rodents possess a general, unconditioned exploratory drive. Likewise, avoidance behaviors may be conditioned or unconditioned. Conditioned avoidance behaviors can be induced by pairing a neutral stimulus with a punished response such as an electrical shock. Examples of unconditioned avoidance behaviors include a rodent's aversion to brightly lit, open, and elevated locations. Animal models of anxiety that measure unconditioned conflicts are defined as ethological, while models that measure conditioned responses are defined as conditioned operant conflict tests.

The basic premise of ethological models is to study an animal's unconditioned behavioral responses when exposed to a new environment, which causes feelings of curiosity and fear. One of the most popular animal models of anxiety is the elevated plus maze (EPM). In this process, an elevated, plus-shaped apparatus with two open and two enclosed arms is raised aboveground level. This model is based on the rodent's general aversion to open spaces, as well as their natural curiosity and tendency to explore novel environments. This induces a behavior known as thigmotaxis, or remaining close to the edges of bounded spaces. This behavior results in the rodents remaining in the enclosed arms portion of the apparatus (Pellow et al. 1985). Confinement to

the enclosed portion of the apparatus in turn induces certain physiological responses characteristic of stress response, such as increased corticosteroid levels as well as increased defecation (Pellow and File 1986). However, administration of benzodiazepines alleviates these symptoms and results in the rodent's exploration of the rest of the apparatus. It is also important to note that several factors may affect the behavior of rodents in the EPM, such as prior exposure to stress, rodent species, lighting levels, familiarity with the maze, and the presence of the experimenter. Modified versions of the EPM exist which attempt to address these factors, among them including the elevated zero maze (EZM), the elevated T-maze (ETM), and the light-dark box.

The conditioned operant conflict test was developed by Geller and Seifter and demonstrates high predictive validity for classic anxiolytic drugs (Geller 1960). In this test, rodents are trained to press a lever to obtain a sugar-sweetened drink at variable intervals. They are deprived of food for 24 h, and during the test session, a signaling stimulus indicated that pressing the lever will now be accompanied with an electric shock, as well as the sugary drink. This induces an approach-avoidance conflict between receiving the sugary drink and getting shocked. The control rodents are observed to press the lever less often, whereas administration of an anxiolytic causes the rodents to press the lever more frequently. However, administration of opioid agonists such as morphine does not affect the frequency of lever-pressing, so it is clear that this effect is not due to antinociception (Millan and Brocco 2003). In 1971, John Vogel introduced a similar version of this conflict test, in which mice were deprived of water for a 24-h period and trained to locate a source of water in a box (Vogel et al. 1971). The following day, the mice were placed in the same box with a steel flooring which delivered an electrical shock to the mice every 20 licks of the water bottle. Administration of anxiolytic drugs results in the mice licking the water bottle with increased frequency. Both versions of this conflict test have high predictive validity for benzodiazepines and barbiturates, but Vogel's version of the conflict test also

responds to some non-anxiolytic drugs (Millan and Brocco 2003). Additionally, administration of antidepressants produces inconsistent results. For example, long-term administration of monoamine oxidase inhibitors and tricyclic antidepressants increases the frequency of punished responses, but administration of SSRI's such as fluoxetine does not (Scheffe et al. 1989). While both versions of the conflict test possess high predictive validity for anxiolytic drugs, Vogel's version of the test has the advantage of avoiding a prolonged training period.

Another animal model that scientists use to study anxiety disorders is the fear-conditioning model, which is a form of Pavlovian conditioning. Pavlovian conditioning describes an associative learning process in which a neutral stimulus (NS) is repeatedly paired with an unconditioned stimulus (US). After successful conditioning, the neutral stimulus alone can now elicit a biological response in the animal and is now known as the conditioned stimulus (CS). Fear conditioning involves the organism's association of a neutral stimulus, such as a flash of light or a sound, with an aversive stimulus, such as an electric shock. After repeated presentation of the NS with the aversive stimulus, the neutral stimulus alone can produce a fear response in the organism and is now known as the conditioned stimulus. Fear conditioning can be successfully performed in several organisms, including humans (LeDoux 2000). The organism's response to the conditioned stimulus during fear conditioning is usually characterized by freezing, increased heart rate, and increase release of stress-related hormones (Rudy et al. 2004). Animal models of anxiety produced through fear conditioning involve the animal undergoing psychological stress without any physical stimulus. As such, they are valuable models for studying anxiety-related disorders such as panic disorder and post-traumatic stress disorder (PTSD) (Mineka and Oehlberg 2008). Fear-conditioning models have high predictive validity when it comes to anxiolytics and antidepressants. Administration of benzodiazepines or SSRIs to rodents after acquisition reduces the amount of freezing when exposed to the conditioned stimulus, which agrees with clinical

findings that these drugs can be used to decrease symptoms of anxiety disorders (Takeshi et al. 2011). However, it was also observed that acute administration of SSRIs was also effective in this model, which is contrary to clinical findings (Oehrborg et al. 1995). Other animal models of anxiety include predator-encounter-based models, predator-exposure-based models for PTSD, neonatal isolation stress models, stress induced by circadian rhythm changes, stress induced by noisy stimulus, low temperature-induced stress, restraint and immobilization stress, social defeat stress, and chronic unpredictable stress (Campos et al. 2013). There are a significant number of animal models for anxiety and stress, so it is important for a scientist to carefully determine which model would be most appropriate given the question that is being asked and the methods being used to test the hypothesis.

## Animal Models of Schizophrenia

Schizophrenia is a severe mental disorder with a lifetime prevalence of about 0.4% worldwide (Saha et al. 2005). The typical onset of the disorder occurs between the late teen years and early 30s, and it is established that the disorder is highly influenced by genetics. Schizophrenia is a heterogeneous disorder characterized by cognitive dysfunction, positive symptoms, and negative symptoms. Examples of positive symptoms include delusions, hallucinations, and thought disorders. Examples of negative symptoms include social withdrawal, anhedonia, and catatonia. Several antipsychotic drugs are available which may help lessen the symptoms of schizophrenia, but they often result in serious side effects and have a low-response rate. The majority of antipsychotic drugs are somewhat effective in managing the positive symptoms of schizophrenia but have very little efficacy in managing negative and cognitive symptoms (Keefe et al. 2007). The current biochemical research into schizophrenia focuses on the implications of neurotransmitters such as dopamine, glutamate, 5-hydroxytryptamine (5-HT), gamma-aminobutyric acid (GABA), glycine, and

D-serine into the pathophysiology of the disease (Yang and Tsai 2017). Substantial progress has been made to develop valid rodent models that replicate the behaviors and brain pathologies associated with schizophrenia in humans, and it is vital to continue making progress in this area due to current limited knowledge of the biological basis of schizophrenia. The majority of research into the biological basis of schizophrenia focuses on certain neurobiological abnormalities, such as the thinning of the prefrontal and temporal regions of the cerebral cortex, reduced synthesis of GABA, and abnormal levels of dopamine in regions of the brain (Cannon et al. 2002). Developing valid animal models for schizophrenia is vital to improving current understanding of its development, as animal models allow for much more invasive studies on the structural and molecular abnormalities associated with schizophrenia which cannot be tested in human subjects.

Certain highly penetrant human mutations allow for the generation of animal models that replicate certain aspects of schizophrenia (Arguello et al. 2010). One example of such a mutation is the chromosome 22q11.2 micro-deletions, which is associated with symptoms of schizophrenia in about 30% of cases (Green et al. 2009). It is possible to generate mice with deletions in homologous regions of their genome; however, it is important to realize that humans with this mutation are not always diagnosed with schizophrenia. Some may be diagnosed with bipolar disorder or various other psychiatric illnesses, and there is still much work to be done in identifying which deletions are associated with schizophrenia-like behavioral abnormalities in mice. Another mutation associated with schizophrenia is the translocation that disrupts the gene disrupted in schizophrenia-1 (*Disc1*). The *Disc1* mutation was first identified in a Scottish family; however, even within this family, the mutation would not always result in schizophrenia. Other psychiatric illnesses such as bipolar disorder were also observed. Nonetheless, mice with the *Disc1* translocation have been generated, and many of them present with behavioral abnormalities similar to those seen with schizophrenia

(Pletnikov et al. 2008). The validity of these mice as models to study schizophrenia is still debated. Some cognitive deficits are associated with schizophrenia and can be used to attempt to validate animal models. For example, deficits in executive function, attention, and working memory are not specific to schizophrenia, but may assist in identifying whether a certain animal model displays behaviors reminiscent of schizophrenia (Simpson et al. 2010). Another useful behavior to observe is a deficit in prepulse inhibition (PPI), which is the phenomenon in which a weak initial stimulus inhibits the startle response evoked by the stronger stimulus. It is thought that a deficit in PPI represents the impaired sensorimotor gating, and PPI can be easily measured in animals.

## Future Directions

Developing animal models for human psychiatric illnesses is a challenging yet rewarding endeavor. The majority of psychiatric illnesses arise from a combination of environmental, genetic, and social factors. As such, it is not possible to perfectly reproduce a psychiatric illness in an animal model, so researchers must focus on producing and studying certain endophenotypes that mimic the illness in some way. For highly studied disorders such as depression, anxiety, schizophrenia, and bipolar, there may exist hundreds of different animal models that mimic the disorder in various ways. It is up to the scientist to determine which model would be most appropriate considering the nature of the experiment and question at hand. New animal models for psychiatric disorders are constantly being generated, and there has been a large focus in recent years on generating these models through genetic engineering. Many observations and conclusions are reached, while studying animal models are not relevant to the human counterpart of the illness, but nonetheless shed light on neurobiological and behavioral aspects of psychopathological syndromes in nonhuman subjects.

## Animal Response to Fire

Ivo Jacobs

Department of Cognitive Science, Lund University, Lund, Sweden

### Introduction

Fire has transformed terrestrial ecosystems since vascular plants colonized land. Many lifeforms have adapted to its recurrent and widespread impact. Understanding the complex interactions

in fire ecology becomes especially pressing with rapidly shifting fire regimes. An important but poorly recognized approach concerns the response of animals to fire, which can be categorized as avoidance, association, habituation, or interaction.

### Avoidance

Animals avoid fire and fire-modified landscapes. This pyrophobic response appears to be predominant. Many plants in fire-prone ecosystems have physical adaptations to mitigate fire damage. In contrast, terrestrial animals typically have the sensorimotor abilities to avoid fire (Engstrom 2010; Pausas and Parr 2018).

Fire can be detected by various senses, such as vision, olfaction, audition, and thermoreception (Engstrom 2010). For instance, captive shingleback lizards increase their activity and tongue flicking when exposed to light smoke without fire, which suggests that their escape behavior from wildfire is guided by olfaction alone (Mendyk et al. 2020). The ability to detect fire at a far distance or early stage is especially important for slower animals that need more time to flee or find shelter, compared to highly mobile animals such as birds. For example, some mammals rouse from torpor to escape, some amphibians flee to less flammable areas, some reptiles take cover in burrows, and some arthropods hide deep in soil or high in trees. The shells of tortoises and snails appear to offer some heat protection, but it is unclear to what extent fire influenced their evolution. In some fire-prone habitats, birds and eusocial insects protect their nests from fire by keeping the surrounding area clear from debris and vegetation (Engstrom 2010; Pausas and Parr 2018).

Many animals also avoid recently burned landscapes. Populations may crash when the availability of food, water, shelter, and nesting sites is decreased after fire. This effect can be reduced by relocating to adjacent unburned areas. For instance, the openness of burned landscapes makes it harder for lions to stalk prey, which is likely why they prefer to hunt in areas with more

undergrowth (Geary et al. 2020). Populations are generally more sensitive to these indirect habitat-level effects than direct individual-level mortality (Engstrom 2010; Geary et al. 2020; Pausas and Parr 2018).

## Association

Animals associate with fire-modified landscapes. They may still avoid fire but benefit from its aftermath. “Fire beetles” (*Melanophila*) possess both infrared and olfactory receptors to detect fire and smoke. These adaptations help them find recently burned trees – or even trees that are still burning – in which their larvae need to develop (Schütz et al. 1999). This provides the clearest case of fire adaptation in an animal. There are dozens of other pyrophilous insect species that are also attracted to recent burns for feeding, reproduction, or development. The darker color variants of pygmy grasshoppers become more common after fire, when this coloration offers better camouflage. Similarly, ground squirrels inhabiting burned landscapes are more often darker colored, and some African birds that breed in recently burned areas have darker eggs and chicks (Pausas and Parr 2018).

Many insectivorous animals associate with fire-modified landscapes when the abundance and accessibility of insects has increased (Engstrom 2010). Reptiles may be attracted to such open areas to bask (Geary et al. 2020). Animals that nest or seek shelter in dead trees benefit from fire increasing the availability of this rare resource. Burned areas may also incur health benefits because fire destroys parasites and pathogens. The increase in light and nutrients encourages seeds to germinate and surviving plants to sprout. This “greening phase” attracts pollinators and herbivores. Grassy ecosystems such as savannahs and prairies strongly depend on the rejuvenating effects of wildfire and grazing (Pausas and Parr 2018).

Burned landscapes also attract many predators. Wolves, for example, benefit from the greater abundance of prey and openness to hunt. However, population-level responses of vertebrate

predators are largely inconsistent and unclear based on current knowledge. Many factors play a role, such as species, location, habitat, competition, severity of fire, and time since fire. Behavioral flexibility alters predator-prey dynamics and buffers ecological impacts of fire. For instance, some predators shift strategy and focus on different species after fires, which mitigates the adverse effects that a specialist predator might experience (Geary et al. 2020).

Primates that inhabit fire-prone habitats often associate with burned landscapes, where they can experience more efficient foraging, traveling, and predator detection. Vervet monkeys significantly expanded their home range after a prescribed burn, mainly by incorporating burned habitat where they can feed on insects killed or stunned by smoke and fire. Another advantage of foraging in these areas is that wildfire occasionally “cooks” food, which kills pathogens and increases ease of chewing and digestion (Herzog et al. 2014). Savanna chimpanzees travel through burned areas, sometimes only minutes after the fire when the ash is still warm. The reduction in vegetation greatly improves visibility and ease of movement. Chimpanzees spend more time traveling and foraging, and less time resting and socializing, in burned compared to unburned areas (Pruetz and Herzog 2017).

## Habituation

Animals habituate to fire, responding appropriately and calmly. This response may optimize the tradeoff between potential harm and benefit of present fire. These animals typically also associate with post-burn landscapes. *Melanophila* fire beetles often meet and mate in burning trees (Pausas and Parr 2018; Schütz et al. 1999). Many birds of prey are attracted to wildfire (see Fig. 1). They likely improve their foraging success by hunting exhausted and disoriented prey fleeing the fire (Bonta et al. 2017; Geary et al. 2020). Other predatory animals also hunt near fire, but little is known about the importance of such fire foraging for their food intake (Pausas and Parr 2018). Crows and other corvids occasionally

**Animal Response to Fire, Fig. 1** Two black kites and a Torresian crow at a bushfire near Borroloola, Australia. (Photo courtesy of Robert Gosford)

engage in *anting*, which involves applying ants or substances to their feathers and skin, possibly to reduce discomfort. This may explain why some corvids have the peculiar habit to “fumigate” their plumage over chimney smoke, which also warms and dries them on wet days. Captive corvids sometimes bathe in smoke next to fire as well (Burton 1959).

Primates that associate with burned landscapes usually habituate to present wildfire. Savanna chimpanzees and vervet monkeys are accustomed to seasonal fire and calmly forage and travel next to it. Some vervets scanned the area when the smell and sound of approaching fire became perceivable to a human observer, and remained calm even when the fire was within 20 m distance (Herzog et al. 2014). In decreasing frequency, chimpanzees ignored, avoided, monitored, or navigated around wildfire. They sometimes rested and groomed in close proximity (<10 m) to fires that were small, which suggests their response is based on several factors, such as

experience, weather, flame height, and vegetation density. They were more careful and vigilant toward the end of the dry season, when fires are particularly fast and unpredictable (Pruetz and Herzog 2017).

## Interaction

Animals manipulate, transport, explore, investigate, or play with fire. Close interactions with fire are uncommon in nature but have been documented in captivity. The closest known interactions with wildfire come from northern Australian raptors – black kites in particular – that gather in large numbers near bushfires to hunt (see Fig. 1). A small fraction of these birds transports fire by picking up burning sticks in their talons or beaks and dropping them elsewhere. Spreading fire may increase their hunting success, but this curious behavior has not been investigated in detail (Bonta et al. 2017). Wild birds sometimes cause fires by incorporating hot cigarette butts in their nests. Several observers have reported how captive corvids *anted* with glowing embers and cigarettes by picking them up in their beaks and pressed them against their feathers. Some even learned to light matches by striking the heads with their beaks (Burton 1959).

During a time when zoo-housed chimpanzees were frequently supplied with cigarettes, they lit the correct end with burning matches or cigarettes, monitored the lit end, saved burning cigarettes in a way that prevented inadvertent extinguishment by cold surfaces, used fruit peels to safely handle hot residues, avoided combustible materials, carefully removed burning sacks, and ensured finished cigarettes were properly extinguished after dousing them in wet patches (Brink 1957). These observations suggest that, under the right conditions, large-brained animals such as chimpanzees and corvids can learn to safely and elaborately interact with fire and use smoldering objects as tools. Further studies on the complex and flexible behavior of animals toward fire will also illuminate how hominins likely came to use and control fire (Brink 1957; Herzog et al. 2014; Pruetz and Herzog 2017).

## Conclusion

The cascading effects in fire ecology are many and complex. The indirect population response to wildfire is described for many species, but the direct behavioral response of animals to present fire is poorly studied. Although the alteration of habitat affects animal communities more than direct mortality by fire, behavioral aspects should not be neglected because they explain how animals living in fire-prone areas mitigate the damage of fire – or even benefit from its effects – without apparent physical adaptations. Descriptions of animals' behavior toward fire are often vague or anecdotal, with a wide variety of responses caused by unclear factors and reported in only few species. Thus, the four response categories are based on limited literature and will surely prove to be too few and too unrefined. It is unfortunate that no clear conclusion can be drawn, not only because animal response to fire takes a central role in many ecosystems with human-caused shifts in fire regimes and resulting conservation concerns, but also because further examination of animal behavior toward fire will shed light on the cognitive capacities that kindled fire use in our own lineage.

## What Is an Animal Society?

Many animals form groups, either ephemerally or permanently, including schools of fish, colonies of seabirds, or herds of ungulates. However, many fewer species form more complex social groups that are often referred to as societies (Fig. 1). Defining a “society” is a difficult task because the term has different meanings to researchers in different fields. For example, the most advanced animal societies – eusocial insect societies – are defined by three criteria: (1) overlapping generations, (2) cooperative care of young, and (3) reproductive division of labor (i.e., many individuals in a group are temporarily or permanently sterile) (Wilson 1971). Yet, many cooperatively breeding vertebrate societies are also described by the same three criteria (Sherman et al. 1995). Despite many structural similarities, there are key differences between insect and vertebrate societies, the most important being that vertebrate societies lack permanently sterile individuals that aid in cooperative care of young and other tasks. Instead, nonbreeding “helpers” in most vertebrate species maintain the ability to reproduce, and often do so, later in life. In contrast, nonbreeding “workers” in most eusocial insects are not only sterile, but often morphologically and behaviorally distinct as well. Perhaps, then, the simplest definition of society, and one that encompasses vertebrates, insects, and other invertebrate species that form complex groups, is: cooperative group living (Rubenstein and Abbot 2017).

## The Evolution of Animal Society

Whether in insects or vertebrates, animal societies are quite rare; less than 10% of birds, roughly 5% of mammals, and less than 2% of insects form societies. Most of these animal societies consist of kin (in other words, they are family groups), though this is not a prerequisite for

complex groups characterized by cooperation. However, interacting repeatedly with kin is important because it makes cooperation and altruism more likely to evolve. Indeed, William D. Hamilton’s classic work on inclusive fitness (both the direct fitness benefits of reproducing and the indirect fitness benefits of cooperating to raise relatives) and the evolution of altruism set the stage for studies of animal societies (Hamilton 1964). Inclusive fitness theory is an explicit framework that governs the evolution of social traits, irrespective of taxonomy (Bourke 2011). According to Hamilton’s Rule, a social action will be favored when its positive effect on indirect fitness is greater than its direct fitness cost:  $rb > c$ , or the product of the relatedness ( $r$ ) between two individuals and the fitness benefit ( $b$ ) an individual receives from the action valued against the fitness cost ( $c$ ) to the individual expressing the action.

Hamilton’s Rule has long formed the basis of how researchers approach studying animal societies and social evolution more broadly. Recognizing the importance of relatedness ( $r$ ) in Hamilton’s Rule, John Maynard Smith called the idea kin selection theory (Maynard Smith 1964). The central role of kin selection in promoting the evolution and maintenance of animal societies and cooperation more broadly has subsequently been demonstrated experimentally in numerous species of organisms ranging from wasps, to birds, to slime molds. Indeed, animal societies are most likely to form in species where the relatedness between parents and offspring is high because this ensures that the indirect genetic benefits gained by cooperating to raise kin are greater (Boomsma 2007). In other words, relatedness among group members (termed kin structure) is central to the formation of animal societies.

Although kin structure is important in the evolution of animal societies, relatedness is just one term in Hamilton’s rule. The ratio of the costs and benefits of cooperating to raise others’ young also influences whether altruism and animal societies will evolve. In most animal systems, the primary factor that influences the fitness costs and benefits of cooperative care of young is ecology. Ecology can constrain the ability of young to disperse and

A

**Animal Society, Fig. 1** A variety of insects (including the (a) ant *Oecophylla smaragdina* [© C. Moreau] and (b) wasp *Polistes fuscatus* [© E. Tibbetts]) and vertebrates (including the (c) superb starling *Lamprotornis superbus*

[© D. Rubenstein] and (d) African wild dog *Lycaon pictus* [© D. Rubenstein]) form societies characterized by cooperative group living. In these and many other species, groups are comprised of primarily related individuals.

attempt to breed independently, thus promoting the formation of family groups and the adoption of cooperative rearing of kin (Emlen 1982). Additionally, the costs of rearing young in harsh and unpredictable environments can favor the formation of animal societies because additional caregivers may be needed to successfully rear young when conditions are bad (Shen et al. 2017).

Thus, just as Hamilton pointed out (Hamilton 1964), to understand the evolution of animal societies, one must jointly consider the interaction between relatedness and the factors (typically ecological) that shape reproductive decisions and fitness outcomes. From an individual perspective, young must decide whether to disperse and attempt to breed independently, or remain at home and help raise others' (typically kin)

offspring. In vertebrates, these young individuals maintain the ability to reproduce no matter which decision they make. Even in some insect species like wasps (Fig. 1), individuals must make the decision to try and breed independently, or to remain at home and cooperate with relatives while sharing reproductive duties.

## Conclusion

Although species that form cooperative groups are quite rare, societies in a range of animal taxa share many characteristics, including overlapping generations, cooperative care of young, and reproductive division of labor, where many individuals in a group are temporarily or permanently sterile.

Indeed, societies in vertebrates and invertebrates are not only structurally similar, but they are also shaped by the same forces. Hamilton's Rule ( $rb > c$ ) describes how altruism, such as cooperative care of young and reproductive division of labor, could evolve within a society. Indeed, kin structure and relatedness between group mates, as well the role that ecology and the environment plays in shaping the reproductive costs and benefits associated with altruism, influence the formation of societies in insects and vertebrates alike.

## Animal Welfare

Emily Patterson-Kane

Animal Welfare Division, American Veterinary Medical Association (AVMA), Schaumburg, IL, USA

## Synonyms

[Animal wellbeing](#)

## Definition

An explicit or tacit conceptual model or framework for understanding and assessing the overall good or poor state of an individual animal, with implications for ethical conduct in relation to that animal.

## Introduction

The desire to understand the welfare of animals springs from understanding animals as sentient beings that are able to suffer or enjoy experiences. Sentience (the ability to consciously sense and feel, including the capacity for suffering) is a morally significant state. As such, animal welfare typically includes consideration of an individual animal's subjective experiences, such as thoughts and emotions, which cannot be objectively and scientifically measured.

An assessment of an individual's welfare requires some process for making an overall judgment of a good or bad state based upon a variety of qualitatively different factors such as impairments, injuries, stresses, and inferred mental states that vary across time. Welfare assessments may be made relative to different

baselines or ideals, and with reference to different contexts, relationships, beliefs, and biases that vary between individual observers. Various conceptual models have been developed to attempt to resolve these interobserver differences as much as possible and develop a consensus around what constitutes good, bad or acceptable welfare.

The use of the specific term “animal welfare” is uncommon in published literature before 1920 and becomes commonplace only during the 1970s. The corresponding “animal welfare movement” occurs at different times in various countries. In the twentieth century, developments often arose initially in the United Kingdom before spreading to other countries, but more recent developments happened more or less simultaneously in a myriad of developed nations. The term “animal welfare” is still absent from many prominent dictionaries including the Cambridge and Merriam-Webster dictionaries, and definitions provided in other sources are conspicuously outdated in referring to animal welfare as a human duty rather than a state of the animal (e.g., Collins dictionary).

## Historical Context

An appreciation of the needs and experiences of animals goes far back in history. This includes religious prohibitions against overdriving animals, concern about animal cruelty as harmful to a person’s character, and promoting good care and husbandry of animals as a work ethic. Specific apparently cruel practices would be highlighted by commentators, but arguments against them were largely based in either encouraging the most effective techniques or the need for the people involved to display good moral character, rather than the suffering of the animals (e.g., the seventeenth century practice of attaching a plough to the horse’s tail rather than a harness; Blosch 2012). However, in order to endanger character, these practices must also have been considered cruel or at least demonstrative of insensitivity – even if animals were not generally considered to warrant moral consideration in their own right.

Attempts to understand and assess animal welfare in a formal ethical or scientific manner are usually traced to a brief statement made by Jeremy Bentham in the “Introduction to the Principles of Morals and Legislation” (1786, p. 311), where he argued that moral significance of an individual stems not from their intelligence or standing in society, but from their ability to suffer, specifically:

“The day may come when the rest of the animal creation may acquire those rights which never could have been withholden from them but by the hand of tyranny . . . The question is not, Can they reason? nor, Can they talk? but, Can they suffer?”

In the twentieth century, welfare went from being a purely moral consideration to a subject of scientific assessment with important implications for law, politics, and trade.

There are a great many specific historical events, which occur between the late eighteenth century and the present time, that are significant for the development of the concept of animal welfare and how individuals, institutions, and cultures engage with it. This history is largely one of issue-based public outrage and protest followed by the implementation of either a ban on the activity or its continuance governed by increasingly rigorous humane laws and regulations. However, the focus was increasingly on the ethical significance of the animal itself, as a victim of unnecessary or inappropriate suffering or death. For example, the criminalization of animal abuse began after protests about the mistreatment of working horses and livestock, and later the plight of stray dogs and cats. The actions of humane societies (e.g., Society for the Prevention of Cruelty to Animals 1824, American Humane Association 1877) led to the passage of laws distinguishing animals from insensate property by punishing the cruel treatment of animals, even if the perpetrator owned the animal. Legislation of this type passed in the United Kingdom in the 1820s and the United States beginning in the 1860s. National anticruelty regulations were gradually implemented in most countries although scope and enforcement varies (e.g., France 1850, India 1960), but such legislation still does not exist in some influential nations, including

China. Most countries that introduce anticruelty legislation continue to expand its scope over time to cover many species and a range of specific activities such as animal fighting, illegal forms of hunting, and fetish cruelty. However, tension continues to exist between the right of an animal to not be harmed or killed, and their status as property that is used in culturally significant activities that impair animal welfare and cause animal deaths. This is referred to as the sentient property problem (Favre 2004), or the caring/killing paradox (Arluke 1994).

The use of animals in research, and specifically vivisection, is a particularly contested subject. Research and teaching was initially unregulated. Models for requiring scientific and ethical justifications for these uses first developed in the United Kingdom after a series of protests in London referred to as the Brown Dog Affair (1903–1910). Since this period, animal-based research, testing, and teaching became increasingly regulated and overseen by ethical review committees that weigh the harm done to the animals against the projected benefits from carrying out the activity. It is now widely accepted that animal use that is harmful should be replaced whenever possible (Balls 1994). “Cruelty Free” products, that are not tested on animals, became popular in the 1970s; and many cosmetics companies committed to no longer testing on animals (e.g., Avon 1989; Revlon 1990). Animals also ceased to be used in crash tests, and nonanimal alternatives were developed for many routine medical tests such as pregnancy testing. However, animal testing remains central to biomedical research and safety testing where it continues to receive diminished, but majority, support in most countries.

The 1960s and 1970s saw the emergence of animal welfare as an important mainstream issue in many countries. Landmarks included the publication of Ruth Harrison’s book “Animal Machines” (Harrison 1964), which criticized intensive agricultural practices, and launched animal welfare as an important issue for consumers and industries including agriculture, manufacturing, and retailing. In the 1970s, several coherent philosophies were developed for the opposition of

most, if not all, animal use (a.k.a.: animal rights, abolitionism) specifically Peter Singer’s “Animal Liberation” (Singer 1973) and Tom Regan’s “The Case for Animal Rights” (1983). Animal rights activism became most distinct from animal welfare societies that aimed to ensure that animals were treated kindly but did not generally oppose their use for human purposes.

Many direct action groups focused their attentions on specific activities that harm the welfare of animals. For example, hunt saboteurs (e.g., Hunt Saboteurs Association 1963) in the United Kingdom disrupted the hunting of foxes with hounds, which was ultimately banned in 2004. Other groups targeted research using primates, whale hunting, bull fighting, the use of leghold traps, horse soring, battery cages for hens, or a myriad of other allegedly abusive practices. In some cases, more extreme groups liberated animals and harassed or even attacked people involved in these contested animal-based activities (e.g., Animal Liberation Front 1976; Stop Huntingdon Animal Cruelty 1999).

Direct action activism came to be increasingly balanced or even replaced with legal and political strategies throughout the 1980s and afterward. Organizations that focused on ending perceived abusive practices in particular locations were joined by more overarching entities aiming to change social norms and attitudes toward animals at the national or international level (e.g., Animal Legal Defense Fund 1979; PETA 1980). In the United States, the use of state-level ballot initiatives became popular as a method for creating pro-welfare laws without involving the usual slow and traditionally conservative political processes. Landmark events include the EU ban on gestation crates (2013) and passage of felony animal cruelty laws in 43 American states.

In the 2000s, property rights over some animals was further challenged by efforts to award certain “human” rights to animal groups (e.g., banning experimentation on primates, New Zealand 1999; Austria 2005). However, in general, the use of animals remains common, including activities that cause a loss of animal life, exposure to harm, or limitations on freedom of movement, reproduction, and other life

processes. Whereas the boundaries of acceptability have changed in most modern cultures, there remains a mainstream support for and legal protection for the use of animals for a myriad of human purposes including food, fiber, entertainment, and companionship.

These uses are increasingly regulated to ensure that animal welfare standards are followed in all animal-using industries including agriculture, research, entertainment, and the breeding and trade of pet animals. Trust in these standards is sometimes undermined by the release of video exposes and professional documentaries that show abusive treatment of animals in settings such as farms, circuses, and slaughterhouses. However, in an increasingly short media cycle, these investigations seem to be having a diminishing impact on public attitudes and often do not lead to tangible changes in practice.

Animal welfare is now a concept that most members of the public are familiar with and hold views about, including what kinds of animal use are justified, under what conditions, and on what ethical basis. Animal welfare is widely discussed and animal welfare issues are prominent in the media, proposed bills, and academic arena. People and organizations that use or handle animals are subject to critique and often have carefully formulated procedures based on explicit ethical principles and scientific information. The right to use animals, or to claim specific uses are humane or welfare-friendly, continued to be contested in lay and legal contexts.

## Prevailing Models

Animal welfare is a term that is predominantly used in utilitarian context where the goal is to reduce overall levels of suffering in a community or population. It is sometimes distinguished from “animal rights” (which asserts that an individual should not be exploited by another, Regan 1983) and “ethics of care” (where responsibilities are based on our relationship-based duties to others, Held 2006). However, in practice, these approaches and other sources of attitudes and beliefs are often all contributing

factors to any particular situation, rather than neatly separated.

Initially, animal care personnel within animal-based industries and professions tended to focus on the animal’s health and productivity, and assumed good animal welfare would be achieved as a result. This perspective continues to be expressed today by some industry users but is no longer widely accepted by the public who view animal welfare issues through a more direct, empathetic lens. Also, with the development of more extreme genotypes and intensive housing, it became increasingly apparent that the interests of the animal and the human-animal users are not always wholly aligned. Evolving technologies (stall and cage design, genetic manipulation, pharmaceuticals, etc.) allow people to more fully control and exploit animals, without requiring the animal’s cooperation. They also expand the levels of performance beyond the productivity limits of the ancestral or wild type. The extreme examples can be seen not only in relation to high producing agricultural animals, but also animal athletes, such as racehorses, and the extreme confirmations and associated congenital health problems experienced by some pedigree companion animals such as dogs.

Methods for formally assessing the state of animals were developed that emphasized new scientific discoveries and the developing public interest. For example, beginning with the work of Hans Selye popularized in the 1950s, it was appreciated that many adverse events accumulate in the form of stress, which impacts the hypothalamic-adrenal-pituitary axis and leads to a “general adaptation syndrome” (Selye 1950). Other executive processes that are intermediate between particular adverse events, and what the animal experiences or its overall state, contribute to many animal welfare models. In more recent times, this has led to advances in understanding the welfare implications of inflammatory processes, immunity and sickness behavior (Millman 2007), and of the conscious experience of an overall state of suffering or enjoyment, leading to the development of a pessimistic or optimistic outlook (a.k.a. “cognitive bias”). Some models of welfare focus on the quality of inputs to the

animals, but most relate to the overall experience or state of the animal and are based predominantly on outputs from the animals that directly reflect or correlate with that state. Summative states such as stress, suffering, or cognitive bias make up some greater or lesser portion of the overall welfare state. Concepts broader than animal, such as animal integrity or dignity, are also being increasingly recognized (Ortiz 2004).

In terms of specific academic models, Broom (1986) defines welfare as a measurable physical state of an animal in relation to its efforts to cope with its environment, with difficulty in coping and failure to cope resulting in impaired welfare. Dawkins (1990) emphasizes the role of suffering especially severe or chronic suffering as the most important aspect of an animal's welfare. Dawkins (1990) also emphasizes the animal's free choice as a method for determining which environments and other options will support favorable welfare states. Many theories developed after 1990 were more multidimensional in nature. For example, Fraser et al. (1997) suggest that considerations of an animal's welfare must include (1) its subjective state, (2) its biological health, and (3) its lifestyle in relation to what is natural for the animal or its "telos." Mellor and Beausoleil (2015) proposed a five Domains theory that includes nutrition, environment, health, and behavior all contributing toward the fifth domain of mental experience.

Particular conceptualizations of welfare have been adopted by important institutions and within certain industries. For example, the "Five Freedoms," which outlines negative experiences that animals should not have (broadly: hunger, discomfort, pain, fear, and restricted behavior) are widely adopted in the field of agriculture. The "3 Rs" (asserting that the use of animals should be refined, reduced, and replaced) is widely used in relation to animal-based research, teaching, and testing.

More overarching entities such as the OIE (World Organization for Animal Health) tend to have even more eclectic definitions that reference multiple different ideas. The following definition clearly refers to the work of Broom (Broom and Johnson 1993), freedom from suffering,

measuring different domains, and the connection to a human duty to avoid causing suffering:

"Animal welfare means how an animal is coping with the conditions in which it lives. An animal is in a good state of welfare if (as indicated by scientific evidence) it is healthy, comfortable, well nourished, safe, able to express innate behaviour, and if it is not suffering from unpleasant states such as pain, fear, and distress. Good animal welfare requires disease prevention and veterinary treatment, appropriate shelter, management, nutrition, humane handling and humane slaughter/killing. Animal welfare refers to the state of the animal; the treatment that an animal receives is covered by other terms such as animal care, animal husbandry, and humane treatment. (OIE 2010, p. 1)"

In the international arena, a Universal Declaration of Animal welfare has been proposed by the World Society for the Protection of Animals (WSPA). First launched in 2000, the most current (2014) text calls for signatories to recognize that animals are sentient and should be protected under the law. It references the OIE and the Five Freedoms and promotes the overall goal that states should "*prevent cruelty to animals and to reduce their suffering*" (Favre 2016). This declaration has not galvanized widespread international support. Earlier proposals with more of an animal rights-focus were also unsuccessful, including the Universal Declaration of Animal Rights (United Nations Educational, Scientific and Cultural Organization (1978), The Declaration of Animal Rights (Our Planet Theirs Too, 2011), and the Universal Charter of the Rights of Other Species (the Australian and New Zealand Federation of Animal Societies, 2000).

In summary, most current definitions of animal welfare describe it as a multidimensional state with subjective components. It is a state of the animal rather than a duty to the animal, and it is assessed based on measurements of how the animal is faring potentially including survival, health, immunocompetence, and behaviors – including abnormal behaviors such as stereotypy (Mason and Latham 2004). Increasingly, the focus of animal welfare has been shifting from only preventing negative states to providing "a life worth living" (Yeates 2011), which includes the animal experiencing positive welfare states

such as play and amicable social interactions (Yeates and Main 2008).

## Complicating Factors

### Subjectivity

Given that the animal's subjective states (e.g., emotions, cognition, pain) are typically considered an important part of its welfare, our inability to measure these states in a direct and objective manner is problematic. There is no simple solution to the problem of subjectivity in the science of animal experience, including human psychology. Attributing thoughts and feelings to nonhuman animals is often criticized as anthropomorphism; however, this critique is valid only when the attribution is made in error. A number of strategies have been used to resolve this problem. Ethically, there has been a move from assuming that animals do not have subjective experiences, to assuming that they do – based on equivalence to human experience or a precautionary principle. The argument being: it is less ethically problematic to allow for sentience or suffering where it is absent, than to permit suffering to occur simply due to lack of conclusive evidence. Methods for indirectly assessing subjective states have been developed and at least partially validated in many different areas. For example, physiological stress responses have been correlated to highly likely stressors. The animal's motivation to seek out or avoid experiences has been assessed (a.k.a. anticipatory states and conditioned place preference, Spruijt et al. 2001). And the ability of observers to intuitively judge animals' emotional states had been shown to closely match the emotion-provoking situations the animals were in (but that were hidden from the observer, see Wemelsfelder 2007).

### Time Factors

Animal Welfare, as described so far, is the state of an animal in a given moment or short period of time. However, individuals are in better or worse states across time and there is evidence that some periods of stress or adversity may actually be beneficial (e.g., Chamove and Moodie

1990). Assessing an animal's long-term or even lifetime welfare state is more difficult than making an assessment during a particular inspection or process. However, chronic welfare states are increasingly being addressed by research that assesses how animals interpret environments and develop their temperament and overall orientation to new experiences (i.e., optimism or pessimism; a.k.a. cognitive bias, Mendl et al. 2009).

### Groups

Many animals, especially domesticated species, naturally live in groups. It is also common to make decisions in relation to wildlife according to all of the animals in an area or of a species (e.g., conservation efforts). When assessing welfare in a group, any choice will affect the individuals of the group unevenly. For example, social housing is generally beneficial, but some animals in a group might be bullied and harassed by conspecifics, or relocating some wild animals might cause them stress and risk their lives but reduce the chances of species extinction (Dickens et al. 2010).

### The Role of Death

In the commonly used scientific and regulatory utilitarian framework, which emphasizes the avoidance of suffering, death is sometimes not treated as a significant issue other than in its role of terminating subjective states and eliminating the potential for future subjective states. However, in a more general context, death is considered highly significant, especially when the death is considered to have no purpose or utility. Existing frameworks of animal welfare typically do not capture the significance of death for the animal or for the average humane observer (Jensen 2016).

### Cultural Lenses

Acceptable compromises to animal welfare are distinguished from animal cruelty through a lens of activities that are socially acceptable versus unacceptable. For example: hunting versus thrill killing, or correcting an animal as part of training versus hitting it from frustration or anger. Within this social context, individuals will hold a diversity of views; however, the majority will tend to

align with what is historically acceptable and legal in the community. Academics within the Green Criminology tradition (where harms against animals or the environment are equated with harms against persons) challenge this approach and tend to suggest that all actions causing animal suffering should be considered unacceptable (Beirne and South 2013).

## Public Attitudes

Members of the general public often react to animal welfare scenarios on an intuitive or empathic manner rather than according to an explicit ethical framework. Activities that are common in the community might elicit little or no response even when they cause evident suffering. Any assessment of animal welfare has to, in some way, consider community standards, at least in the context of trying to implement changes in how animals are treated. Survey data also show that animal welfare is not treated as a distinct concept but overlaps with other terms such as free range or organic (Harper and Makatouni 2002). And, whereas an animal husbandry professional might equate cleanliness and hygiene with good animal welfare, the general public tends to put less emphasis on this factor and more on the naturalness of the animal's environment. For this reason, people using the term "animal welfare" may actually be speaking of quite distinct issues and priorities in relation to any particular animal or animal-related practice. One common example being the people directly involved in an activity who place a cultural value on the activity and feel they should be respected as experts, versus critics who may not understand why welfare-friendly practices are difficult or too expensive to immediately implement. For example, pigs as social animals theoretically benefit from social housing; however, the genetics of commercial pigs and their intensive housing mean that group housing can lead to high levels of aggression and injury (Rodenburg and Turner 2012). Thus, the ideal outcome of social housing will require many adjustments and may depend upon the

extent to which the public is willing to pay a higher price for options that better match their naturalistic preferences for animal raising.

## Selected Subtopics

Animal welfare as a global topic includes a great many areas of special interest. A few representative examples are given below:

### Analgesia

Historically, pain relief was considered unnecessary for many animals. For example, it was considered beneficial to not provide analgesia on the assumption that feeling pain would prevent an animal from moving around too much after surgery. With the development of concern for animal suffering and more sophisticated analgesics, pain relief is increasingly considered the norm at least for companion animals. Specifically, in most sectors, the use of multimodal pain relief is preferred, an approach to analgesia that addresses both the immediate pain from an event such as surgery and pain over subsequent days during the inflammatory response and beginning of healing. The provision of analgesia in other contexts, for example, during routine agricultural procedures such as dehorning and castration, remains challenging. However, the painfulness of these procedures is widely acknowledged (e.g., Sutherland and Tucker 2011) and research is underway to develop practical protocols for providing analgesia.

### Cosmetic Surgery

Historically, it had been considered acceptable to perform "utility surgeries" on animals to adapt them to the needs of human convenience. For examples, tail docking, dehorning, and debarking. With the acknowledgment of the significance of animal sentience, the public moved to endorsing only surgeries that are to the benefit of the animal; for example, tail docking of sheep to prevent fly-strike versus tail docking of dogs to meet breed standards. Traditionally acceptable "utility surgeries" are becoming unacceptable or are banned where they are deemed to be purely cosmetic (Hubrecht 1995).

### Environmental Enrichment

One of the great challenges of keeping animals in captivity is creating an environment that keeps them physically and mentally occupied in a manner that supports their health and welfare. Environmental enrichment is a term for features that are added to a habitat to overcome the harmful effects of barren or nonstimulating environments. Enrichment comes in many forms that can be summarized as sensory, structural, social, food-based, and cognitive. Environmental enrichment programs are common in laboratories, zoos, and aquariums, and increasing in agriculture and other settings as well (Young 2013).

### Extreme Confinement

Around the end of World War II, advances in hygiene, engineering, and nutrition supported the development of intensive housing for agriculture, research, breeding, and other settings. These systems, including ventilated laboratory animal caging, battery laying hen cages and gestation, and farrowing stalls for pigs, had many advantages in terms of protecting animals from hazards (i.e., predators and disease). However, it became apparent that barren conditions had serious consequences for natural behavior and mental states of animals. The idea developed that animals have not only physical needs such as food and warmth, but also spatial, behavioral, and psychological needs (Hughes and Duncan 1988). Although a middle ground is available in the form of enriched cages, the public seems to generally prefer cage-free options. These are challenging in terms of the use of resources and exposure of animals to the hazards of the environment.

### Low Stress Handling and Positive Training

Where interactions with humans are necessary or have the potential to be beneficial, there has been a strong shift from stressful experience and the use of force or punishment, and toward using gentle methods, rewards, and working with natural behavior. This paradigm shift is apparent in the replacement of old “dominance”-based approaches to training dogs and other animals toward developing a positive human-animal bond and obedience based on social rewards,

treats, and other positive outcomes. The use of positive motivation is also adopted in relation to livestock applications such as driving cattle and the design of slaughterhouses. Most notably the work of Temple Grandin in showing how understanding the animal’s point of view can lead to the development of handling and transportation systems that allow animals to move through a facility without feeling alarm or panic (Grandin 2007).

### Why Is Welfare Such a Source of Conflict?

Animal welfare is a state of the animal but it is ethically relevant to human culture and intersects with both human feelings (empathy) and social norms. A person’s beliefs about animal welfare are emotional and ethical and often deeply held. However, they are also often based on a complex combination of temperament, culture, and implicit and explicit conditioning. Currently, there are a number of unresolved cultural dissonances. For example, attitudes toward modern farming are increasingly negative; however, most people continue to consume the resulting products such as meat, milk, and eggs (Te Velde et al. 2002). When this ambiguity is combined with instantaneous communication between cultures around the world with unique histories and traditions, and intergenerational change, it leads to a great potential for disagreement about what is acceptable, appropriate, or admirable when it comes to human conduct in relation to animals.

### Conclusion

Animal welfare is the state of an individual animal on a valence scale from negative (suffering) to positive (good quality of life, enjoyment of life). An emphasis is often placed on the animal’s subjective experiences, but other factors relating to physical health and an ideal life for individuals of that species are also often considered relevant to the overall assessment of an individual’s welfare. Reference may also be made to contextual factors such as the duty of humans in relation to animals generally or in a specific context.

The precise model of welfare adopted by individuals and organizations is likely to vary according to their focus and goals. These definitions will also continue to change and evolve over time based on new technologies, information, and cultural imperatives. However, to be in accordance with sound science and ethics, the prevention of suffering and the goal of providing, whenever possible, a good life for the animal should always be included.

## Animal Wellbeing

### ► Animal Welfare

## Animal-Assisted Intervention

Elise R. Thayer and Jeffrey R. Stevens  
Department of Psychology, Center for Brain,  
Biology and Behavior,  
University of Nebraska-Lincoln,  
Lincoln, NE, USA

### Definition

Animal-assisted interventions are professionally facilitated interactions between an unfamiliar animal and a person or group used to improve individual health or well-being. Types of interventions include animal-assisted therapy, education, and activities.

### Introduction

Animal-assisted interventions (AAIs) are a subset of ► [human-animal interactions](#), a fundamental aspect of the human experience that captures the

mutual and dynamic exchanges between people and other animals. Distinguished from affiliative relationships (► [pets](#)), ► [service dogs](#), and emotional support animals, AAIs involve interactions facilitated by a trained professional or paraprofessional (e.g., handlers, researchers, teachers, therapists) where an unfamiliar animal serves to confer psychophysiological benefits to a person or group. Dogs are the most commonly used animals in AAIs, though many incorporate horses or other species. Interventions are diverse in delivery, environment, purpose, structure, and target-age demographic and have inspired scientific inquiry from a vast array of disciplines. As such, AAIs are partitioned into three types: animal-assisted therapy, education, and activities (AVMA 2019). Further, multidisciplinary interest has spurred a number of theories for understanding the effects of animal interventions, as well as a movement to prioritize animal welfare in interventions.

## Types of Animal-Assisted Interventions

AAIs' goal-directed, professional-facilitated, and time-bound nature distinguishes them from human-animal interactions involving pets and service animals. Types of AAIs – animal-assisted therapy, education, and activities – can be distinguished by their structure and goals.

### Animal-Assisted Therapy

Animal-assisted therapies (AATs) are interventions that incorporate an animal into a professionally developed and delivered treatment plan to improve human physical or psychological functioning (AVMA 2019). Professionals use AATs to achieve specific physical, psychological, or behavioral goals. For instance, animals in neurorehabilitation therapies for children and adults with conditions such as cerebral palsy, multiple sclerosis, and spinal cord injury facilitate physical activity and recreation while promoting well-being (Muñoz Lasa et al. 2015). Animals in psychological therapies confer emotional benefits, such as those shown to ease patients' distress in cognitive behavioral therapy (Hunt and Chizkov 2014). Animals also play integral

roles in behavioral therapies for children and adults, like promoting positive social interactions among individuals with autism spectrum disorder (Grandin et al. 2015).

### Animal-Assisted Education

Animal-assisted education (AAE) is an intervention directed or delivered by education professionals to meet educational goals (AVMA 2019). AAEs are implemented in classrooms for both typically developing students and those with special needs and range from primary classrooms to college campuses. Animal-assisted reading programs, for instance, are commonplace in primary classrooms to improve students' experience with reading and, thus, reading performance (Fung 2017). Animals are also used to promote motivation and concentration for students with special needs and, further, to improve their behavioral and emotional outcomes (Brelsford et al. 2017).

### Animal-Assisted Activities

Animal-assisted activities (AAAs) are loosely structured interventions facilitated by a professional or paraprofessional that center an animal as a motivational or social tool with the aim to improve individuals' quality of life (AVMA 2019). AAAs are rich in variety, lacking the rigid structure necessary in other interventions. For example, AAAs have been effectively used to decrease the stress of children during doctor and dentist visits, ease chemotherapy for oncology outpatients, and increase food intake among nursing home residents with dementia (Friedmann et al. 2010).

## Theories of Action

Multidisciplinary investigations of human-animal interactions have revealed an abundance of therapeutic effects, such as reducing physiological stress (e.g., heart rate, blood pressure; Vormbrock and Grossberg 1988), facilitating social interactions (e.g., individuals with autism spectrum disorder and dementia; Grandin et al. 2015; Muñoz Lasa et al. 2015), and improving

academic performance (e.g., reading literacy, motivation; Brelsford et al. 2017). Such diverse interest has given rise to many theories to explicate these therapeutic effects. Theories range from the neural level (e.g., activation of oxytocin system; Beetz et al. 2012) to the ecological level (e.g., biophilia; Wilson 1984). Researchers most commonly attribute the benefits of AAI to biophilia and social support theories (Fine and Beck 2015).

### Biophilia

Biophilia, or the *biophilia hypothesis*, postulates that humans have an innate tendency toward and affinity for life (Wilson 1984). This concept has been used as a building block to understand the therapeutic effects of natural environments (e.g., Ulrich 1983) and is now commonly extended to the similarly therapeutic potential of animal interactions (Friedmann et al. 2010; Beetz 2017). Experiences in natural environments and interactions with animals share the ability to reduce stress and anxiety. For example, the mere presence of an animal can decrease physiological reactions to short-term stressful situations (Demello 1999). Importantly, the biophilia hypothesis also acknowledges differences in the type and effect of animal species, both on an individual and cultural level (Wells 2019). Objections to biophilia, however, claim that empirical evidence of such affinity is both lacking and difficult to obtain (Herzog 2002; Joye 2011).

### Social Support

Animals provide social support to humans that alleviates the effects of challenging circumstances (Wells 2019). Social support from animals in AAIs has been primarily observed in two ways, where animals facilitate social interactions or serve as social mediators. For example, some individuals with autism spectrum disorder benefit from AAT because the animal can provide them with the support necessary to initiate social interactions (Grandin et al. 2015). Animals provide social support as mediators in reading programs, on the other hand, by fostering a more comfortable learning environment for students (Fung

2017). Further, animals can serve as alternatives to other humans, as demonstrated by animals that attenuated adults' physiological stress responses to a stressful situation more than did a friend (Polheber and Matchcock 2014).

## Animal Welfare

Affiliative and service animal interactions occur repeatedly between an exclusive human-animal pair and, though distinctive in purpose (i.e., bond and service, respectively), showcase evolved behaviors between humans and animals. Animal-assisted interventions, however, are comparatively novel. These interactions require animals to interact in an affiliative manner (i.e., peacefully attend to people and/or be petted) in a confined space with an unfamiliar human for an extended period of time (Butler 2013; Ng et al. 2015). AAIs are rapidly increasing across a variety of institutions, including airports, hospitals, and schools. The rising demand of AAIs underscores the need to prioritize and maintain the welfare of the animals. To prevent or mitigate any related distress, advocates have put forth three welfare tenets to uphold during any interaction (Fraser et al. 1997; Ng et al. 2015). First, animals' physical well-being must not be at risk, such that they are free from hunger, thirst, pain, and disease. Second, their affective well-being must be maintained by ensuring animals have freedom from discomfort, fatigue, and fear. Finally, they must be able to engage in behavior that is natural and appropriate in the present environment. Conveying the necessity to maintain both human and animal welfare to researchers and professionals affords animals ethical treatment as they serve humans in AAIs under these evolutionarily novel circumstances.

## Conclusion

Animal-assisted interventions are a promising supplement to conventional therapies and daily activities alike to improve the health and well-being of individuals. The therapeutic potential

of AAIs has sparked the interest of researchers across many scientific domains to better understand their mechanisms of action. That, in tandem with the ever-increasing presence of AAIs across schools, health-care systems, and other institutions, highlights a need to prioritize animal welfare during interventions. Further research efforts and stringent devotion to animal welfare will enable AAIs to continue their rapid growth across many aspects of the human experience.

## Synonyms

### Sexual reproduction

## Definition

Anisogamy can be defined as a mode of sexual reproduction in which fusing gametes, formed by participating parents, are dissimilar in size.

## Introduction

The most important event of an organism's life is to pass on genes to the next generation. Some organisms choose asexual mode, while some prefer more costly process, i.e., sexual reproduction (Barnard 2004). The sexual reproduction is considered as one of the greatest paradoxes of evolution as it applies twofold costs to its practitioners and still prevails in population as a major form of reproduction. The twofold cost of sexual reproduction is (I) cost of meiosis and (II) "fertility cost" of sex (Smith 1978). Whenever female reproduces sexually, she throws away half of her genotype, which foist 50% cost of meiosis. This loss is fulfilled by benefits of sexual reproduction. But this one is considered as misbelief aroused due to our thinking in terms of individual selection (Treisman and Dawkins 1976). The actual cost of sex lies in production of males whose parental investment is always lesser than females. A sexually reproducing female reduces her fertility to half by segregating her offspring into male and female, which are unable to reproduce independently (Lehtonen et al. 2012; Smith 1978, 1989). If there would be only costs of sexual reproduction, then at one time, the asexually reproducing organism should have outcompeted sexually reproducing organisms. But this has not happened, which means that we are also getting twofold advantage of sex which counterbalances costs of sex (Smith 1988, 1989).

Sexual reproduction can be classified into three types, i.e., isogamy, anisogamy, and oogamy, on

the basis of type of gametes produced by parents. Isogamy generally persists into unicellular organism (but not universal), while the anisogamy is found exclusively into multicellular plants and animals (Bulmer and Parker 2002).

## Isogamy

When the two sexually reproducing parents produce gametes of similar size, it termed as isogamy, and the organism is isogamous, e.g., *Chlamydomonas*, yeast, etc. In isogamy, there is generally no "male" or "female" sex, but the participating parents are called mating types like "+" and "-" parents (Fig. 1). In yeast, mating parents are known as "a and  $\alpha$ " cells.

## Anisogamy

When two sexually reproducing parents produce gametes of different size, it is termed as anisogamy, and the organism is anisogamous. The sexes of parents are defined on the basis of gametes produced by them. Generally, the parent producing smaller gamete is "male," and the one producing larger gamete is "female" (Smith 1971). The both gametes can be motile or one of them can be motile and the other is immotile.

## Oogamy

This is the condition where fusion occurs between small, motile (male) and large, immotile gametes

**Anisogamy, Fig. 1** (a) Isogametes of *Chlamydomonas*, (b) fusion of both "+" and "-" gametes

**Anisogamy, Fig. 2** *Marchantia* sp., (a) archegonium-containing egg cell, (b) antherozoid

(female) like *Marchantia*, *Funaria*, etc. (Fig. 2). One more type of gamete differentiation has been suggested, known as pseudoanisogamy, where there are gametes of different size but there is no correlation between gamete size and fusion. This results in random fusion of gametes (Bell 1978; Birkhead et al. 2008; Bonsall 2006). Pseudoanisogamy is considered as an important event for evolution of anisogamy, but it was evolutionarily unstable due to which it has never been observed (Bell 1982; Bonsall 2006).

## Evolution of Anisogamy

Anisogamy is evolved from isogamy, and the most plausible explanation for its evolution is given by the disruptive selection of gametes (Parker et al. 1972; Bell 1978; Bonsall 2006). There are two major selection pressures acting on any species for determining optimum size of gametes. These selection pressures are numerical productivity (number of gametes produced by any parent in a given period of time) and zygote fitness (probability that the zygote will survive up to adulthood and will be able to reproduce, in as short time as possible) (Parker et al. 1972; Bell 1978). This is the conflict of productions vs. provisioning. Ancestral isogametic cells, like any other biological bodies, are likely to be varied slightly in size, and this variation was selectively

neutral (Parker et al. 1972). As suggested by Parker et al. (1972), the fusion between two larger gametes would be advantageous for species as it would provide better provisioning to resulting gametes. Fusion between two smaller gametes or one smaller and other intermediate gametes would have resulted into large number of zygotes, but since they have less cytoplasmic material, the resulting zygote would have poorer provisioning, and they would not survive till adulthood. So, better provisioning of larger-than-average gametes is exploited by smaller-than-average gametes. The smaller gametes have greater motility than larger gametes and are larger in numbers. Thus, before fusion of two large gametes, the smaller gametes will fuse with their larger counterparts owing to their great motility (Fig. 3). This triggered disruptive selection, i.e., selection of both extreme forms (only larger and smaller gametes). The intermediate gametes were not selected because neither they provide better provisioning nor they had greater motility (Barnard 2004).

## Role of Anisogamy in Animal Cognition and Behavior

The anisogamy plays an important role in behavior of organisms, mainly in animals. Different-sized gametes have resulted into different sexes, i.e., sexes are defined by the type of gametes they produce. Males generally produce numerous small and motile gametes (sperm or pollens), while females produce limited number of large and mostly non-motile gametes (egg or ovule). Different-sized gametes have put different selection pressure on male and female, thus giving rise to different sex roles (Knight 2002). Males are promiscuous, i.e., they are indiscriminate for sex and will mate at each opportunity, while females are choosy, i.e., they will mate with the best suitor (Darwin 1888; Knight 2002; Janicke et al. 2016). This promiscuous behavior of male was explained first by Bateman, which later becomes Bateman's principle. Bateman concluded that promiscuity pays off to males in terms of higher offspring compared to their monogamous competitors.

**Anisogamy, Fig. 3** The small gamete, due to high number and high motility will fuse with other type of gametes in population. But if zygote need high provisioning, then only those will be viable which involves fusion with larger gametes. This will result in selection of smaller and larger gametes producers, outcompeting intermediate gamete producers (Parker et al. 1972; Barnard 2004)

Also, promiscuity is not much beneficial for females as when their offspring were sired by more than one males, there reproductive output was reduced (Knight 2002; Bateman 1948). Thus, it would mean that male reproductive success is increased by mating as many as possible females, while for female reproductive success is increased by investing more into eggs and offspring (Bateman 1948; Barnard 2004). Bateman formulated his conclusion on the basis of energetic expenditures in the formation of gametes. He argued that male gametes (sperms or pollens) are tiny, and thus its production is energetically less costly for male, while the eggs are large in size and thus energetically costlier for females. Thus, male's reproductive success is not limited by the no. of gametes but is limited by the no. of successful mating, i.e., how much eggs he can fertilize. But in the case of females, her reproductive success is not limited by fertilization of eggs but is limited by the production of eggs (Bateman 1948; Trivers 1972; Knight 2002). An important modification in Bateman's principle was made by Trivers, where he explained it in terms of parental investment.

Trivers defined parental investment as "any investment made by parents in their offspring which will increase its chances of survival (thence their reproductive success), but, at the cost of their ability to invest in their next

offspring" (Trivers 1972). The sex that invests more in offspring becomes a limiting source for another which invests less, which will lead to intra-sexual competition for mating. Anisogamy has led to competition for limiting mating opportunities, mainly among male gametes and thus between males. As different-sized gametes evolved, sexual selection came into action (Astrid Kodric-Brown 1987). Since female gametes are limited as its production is costly for females in terms of energy, male competes with each other for mating, but in some cases female competition has also been seen. Once evolved, the anisogamy has been maintained in the population by gamete competition (Monro and Marshall 2016).

## Conclusion

Genetic recombination is a primitive condition found in single-celled organisms, higher plants, and animals. The purpose of genetic recombination is the production of new variation for adaptive evolutionary change in variable environments. Anisogamous gametes evolution is the base for the establishment of maleness and femaleness. It produces the asymmetry between the male and female sexes for the distribution of assets to mating. Always females distribute their

resources to progeny; the survival of several gametes (male) for each female consequences in sexual selection to distribute their assets to improve success in competition during fertilizations. The directional selection and stabilizing are the great response of males to constitute an evolutionary benefit to compensate the cost of their production.

## Anne Pusey

Elizabeth V. Lonsdorf  
Franklin & Marshall College, Lancaster,  
PA, USA

Anne Elizabeth Pusey is an accomplished scholar of animal behavior, with particular expertise in the behavior of lions (*Panthera leo*) and chimpanzees (*Pan troglodytes* spp.). Her primary research interests center on the evolution of social behavior, including patterns of competition, cooperation, and social bonds. Pusey was born in Oxford, England, in 1949 and completed her undergraduate degree in Zoology at Oxford University in 1970. Shortly thereafter, she became a field assistant for Dr. Jane Goodall's study of wild chimpanzees at Gombe National Park and went on to conduct her dissertation research on the Gombe chimpanzees in close collaboration with Goodall. Her doctoral degree, advised by Dr. David Hamburg, was awarded by Stanford University in 1978, and her dissertation focused on the physical and social development of wild adolescent chimpanzees. Chimpanzees have a prolonged period of post-weaning association with their mothers, and

Pusey's work was some of the first research to be published on the adolescent life stage (Pusey 1983, 1990). In particular, she documented the behavioral changes shown by females upon reaching sexual maturity and how these changes serve to prevent inbreeding (Pusey 1980). Pusey then turned her field research focus to lions and codirected the Serengeti Lion Project with Dr. Craig Packer from 1978 to 1989. Together, they published seminal research on cooperation and competition within coalitions of male lions (Packer and Pusey 1982), adaptations to avoid infanticide in female lions (Packer and Pusey 1983), non-offspring nursing in carnivores (Pusey and Packer 1994), and the evolution of sex-biased dispersal (Pusey and Packer 1987a). The study of dispersal patterns and inbreeding avoidance strategies are a consistent theme within Pusey's research program (Pusey and Packer 1987b; Pusey and Wolf 1996).

Pusey became a member of the faculty in the Department of Ecology, Evolution, and Behavior at the University of Minnesota in 1983. In late 1989, she began working in collaboration with Goodall to gather, archive, and digitize the long-term behavioral data collected as part of the Gombe chimpanzee study. The resultant database has become one of most important scientific resources in the study of primate behavior and is the basis of hundreds of peer-reviewed publications and numerous doctoral dissertations and masters theses. In particular, since chimpanzees are long-lived, the long-term dataset affords a much richer understanding of the complexities of chimpanzee behavior. For example, Pusey found that high dominance rank in female chimpanzees is correlated to increased reproductive success throughout the lifetime (Pusey et al. 1997). Her current research focuses on female social bonds and competition, the importance of male alliances, and primate life history. In addition, Pusey's students and collaborators have used the long-term database to investigate topics as diverse as the evolution of the hominid microbiome, mating strategies, chimpanzee hunting and tool use behavior, kin recognition, and the consequences of infectious disease. In 1999, she

was honored with the title of McKnight Distinguished University Professor at the University of Minnesota and in 2005; she was elected as a Fellow of the American Academy of Arts and Sciences. In 2010, Pusey became the Chair of Evolutionary Anthropology and a James B. Duke Professor at Duke University, where she established the Jane Goodall Institute Research Center. In recognition of her contributions to the field, she was elected as a Fellow of the Animal Behavior Society in 2013.

Anointing is a behavior in which an animal acquires substances on their bodies, either passively by absorbing chemicals from the environment or actively by rubbing against them or applying them by mouth (Weldon 2004). Fish, reptiles, birds, and mammals have all been recorded anointing, leading to a number of different terms depending on the specific nature of the behavior. In birds, passive and active anointing are seen in a wide range of species, often with formic acid-secreting ants, when it is referred to as “anting,” but also with a wide range of other invertebrates, citrus fruits, and flowers. Many birds also commonly use fine dirt, sand, or peat to cover their feathers, a behavior referred to as dusting, or peat-bathing (Hart 1997; Clayton et al. 2010), but also fitting the definition for anointing. Many mammals of several orders anoint, including carnivores, ungulates, insectivores, and primates, in which the behavior is referred to variously as anointing, scent rubbing, or fur rubbing (Weldon 2004).

There is no consensus on the function of anointing, and hypotheses are often specific to the anointing species, the materials used, and the context of use. The best studied examples of anointing are in birds, in which the behavior is generally thought to protect birds from lice or feather mites (Clayton et al. 2010). While the substances used by birds have consistently been shown to kill ectoparasites like mites and lice, as well as mold and microbes in vitro, experiments aiming to determine the effects of anointing by birds on ectoparasite abundance have failed to demonstrate parasite control.

In mammals, a wider range of hypotheses have been put forward to explain anointing, with olfactory or signaling hypotheses dominating. Carnivores’ anointing by rolling in carcasses or the feces of their prey may be explained by scent camouflage, increasing social attractiveness, or “group scent marking” to give animals a common scent. While often cited, these hypotheses lack empirical support. Frequent links between anointing and scent-marking behavior in carnivores suggests a role in intrasexual competition, possibly by “scent-matching,” in which anointing facilitates the process by which animals assess the status of competitors, or potential mates by comparing their odor with that of the surrounding area, or a defended resource (Gosling and McKay 1990). Hedgehogs have evolved a quite different form of anointing, for which various explanations have been proposed. Hedgehogs anoint by licking toxins from toads and other irritating substances, and transferring them to their spines (Brodie 1977). This process is thought to enhance defense from predators, by making the spines more effective. Although compelling, this hypothesis is not universally accepted, and explanations involving attracting mates and signaling presence have also been put forward (D’Havè et al. 2005).

Several species of primates have been recorded anointing including, black lemurs (*Eulemur macaco*), capuchin monkeys (*Cebus* and *Sapajus*), golden headed lion tamarins (*Leontopithecus chrysomelas*), owl monkeys (*Aotus* spp.), orangutans (*Pongo pygmaeus*), and black-handed spider monkeys (*Ateles geoffroyi*) (Alfaro et al. 2011). These species have been recorded anointing with a range of substances including several plant species, ants and millipedes in the wild, as well as some strong-smelling substances like detergent or cigarettes in captivity (Alfaro et al. 2011). Hypotheses for anointing in these species have been split between signaling and medicinal hypotheses. Olfactory communication is important in primates, and “group scent marking” has been put forward as a potential reason for the behavior. In some species, such as black-handed spider monkeys, the localization of anointing on specific body-parts and sexual differences in the frequency of the behavior suggest

olfactory communication (Campbell 2000), although it is not clear what is being signaled, or how existing olfactory signals might be enhanced.

Anointing in the primates is best-studied in capuchin monkeys (both of the *Cebus* and *Sapajus* genera.), which use plants such as *Piper* spp., onion (*Alium* spp.), and citrus (*Citrus* spp.), and invertebrates like ants and millipedes to elicit the behavior (see Alfaro et al. 2011 for a review). As well as anointing alone (individual anointing), capuchins also commonly anoint in groups rubbing against each other with the anointing materials (social anointing), in what appears to be a ritualized social activity. Hypotheses for the functional reasons for these different types of anointing range from medicinal to chemo-signaling and social bonding, but the prevailing hypotheses refer to chemical defense from ectoparasites and are similar to the explanations offered for anointing in birds.

The efficacy of many anointing materials used by primates in controlling ectoparasites under laboratory conditions has been convincingly established. Benzoquinone secretions from millipedes, oils from citrus peel, onion oils, and formic acid have all been shown to repel or kill ticks, millipede secretions also repel mosquitoes, onion oils also contain antimicrobial agents, and *Piper* plant leaves are used by people to treat skin conditions (Alfaro et al. 2011). Medicinal hypotheses are further supported in capuchins by behavioral studies of semi-free ranging groups that show an increase in anointing behaviors during the wet season when there are more flying insects and therefore potential for the spread of insect borne disease (Baker 1996). While the anti-parasitic effects of many of these substances are not in dispute, it is important to note that, as with anointing in birds, the effect of anointing on parasite abundance in living primates has not been demonstrated experimentally.

Anointing is a social activity in capuchins, and many individuals often come together to anoint, but the nature of the relationship between social behavior and anointing in these species is not clear. Experimentally, anointing has been shown variously to facilitate social interaction between individuals that typically avoid close contact in

wild groups, strengthen social bonds, and elicit aggression in captivity (Alfaro et al. 2011). Furthermore, anointing has been shown to improve the coverage of anointing materials, and coordinates the treatment of group mates, so can be explained without evoking a signaling hypothesis. As a result, experiments have failed to conclusively show whether individuals are engaging in this social activity purely in order to gain access to resources, suppressing aggressive interactions to do so, or whether further social and signaling benefits exist.

Clearly the benefits of anointing in animals are different across unrelated clades, and may even vary between related species. Many of the hypotheses are not mutually exclusive, and there may be multiple functions in any one species. It is easy to imagine how adaptive medicinal behaviors may become ritualized through natural selection and become social behaviors, just as social grooming has evolved a secondary social function in most primate species. Similarly, odors that are already attractive to a species because they relay medicinal benefits may secondarily evolve importance in signaling to potential mates or competitors as a symbol of status.

## A-Not-B Problem

Britta Osthaus  
School of Psychology, Politics and Sociology,  
Canterbury Christ Church University,  
Canterbury, UK

## Synonyms

Perseveration; Perseverative error; Stage IV error

## Definition

The A-not-B error arises from the difficulty of switching an action directed toward one location toward a new location. The original set-up, called visible displacement, involves hiding a toy in location A while an infant is watching. The child is then allowed to search for it. If they retrieve the toy it is seen as an indication of object permanence – the understanding that objects continue to exist even if they are no longer perceived. After a number of repeats of this hide and seek procedure, the toy is then obviously hidden in a different location, B. Up to a certain developmental stage, infants persevere in searching in location A instead of B. This is called the A-not-B error. This behavior can be observed in reaching tasks, but also in larger spatial set-ups that require detours.

## Introduction

When Piaget published his theory of child development in 1937 (1954 in English), it quickly became absorbed by comparative psychologists because it offered a suitable framework for inter-species comparison. There are two reasons for this: first, Piaget was originally trained as a zoologist (the subject of his Ph.D. thesis was the snail), so his ideas are expressed within a broadly biological frame; and second, he denied that language develops prior to cognition, so his experimental tasks were designed to test cognition without relying on language. Much of his theorizing on early development was based on observable, nonverbal behavior, which makes it ideal for the study of animals (Pepperberg 2002).

According to Piaget, the A-not-B error occurs in Stage IV of the sensorimotor period (0–24 months) of human development. During stages I, II, and III infants acquire fundamental perceptual and motor abilities enabling them to perform search behavior. They are not yet able to search for an object that is no longer visible: it ceases to exist in the perceptual world of the infant and they therefore do not possess the concept of object permanence. Stage IV (from around 8 months) is defined by the ability of the infant to search for an object that has moved (or has been moved) out of sight. Here children are very likely to show the so-called A-not-B error, or Stage IV error, in which they continue to search at a previous hiding place (A) although the object was obviously hidden at a new place (B) (see Diamond 1990, for a review). A number of factors can affect the occurrence of the perseveration error, such as the delay between the hiding and retrieval, the number of possible hiding places, the motor requirements, and obviously the age of the infant (Markovitch and Zelazo 1999).

It was initially thought that children in Stage IV (approximately between 8 and 12 months) simply do not understand the concept of an object as continuing to exist out of sight, and in one place only. In certain set-ups, the error could be caused by associative learning as a repeated behavior is reinforced. At Stage V (from around 12 months), the A-not-B error no longer occurs.

## Comparative Studies

Piaget himself was the first to apply his theory to animal behavior, albeit at a theoretical level (Piaget 1971). The first published experimental Piagetian animal research was done in 1971 by Gruber, Girgus, and Banuazizi who investigated the development of object permanence in cats. And in addition to a large number of studies with primates, object permanence has been studied in dogs and wolves (Gagnon and Doré 1994), chicks (Etienne 1973), hamsters (Thinus-Blanc and Scardigli 1981), and magpies (Pollok et al. 2000). Vauclair (1996) gives a detailed account of published studies in this area, as do Cacchione and Rakoczy (2017).

This order of the developmental stages has been applied to animals as it provides a valid and reliable base for a comparison among species. Especially in the area of object permanence, animals can be grouped by the highest stage they can master.

Etienne (1973) stated that animals react in three different ways to the disappearance of objects: animals like insects, spiders, and some lower vertebrates apply special devices or stereotyped movements to find an object of immediate survival value; most birds and some mammals, like rabbits, possess either learned or unconditional responses they apply to find an object that has disappeared, but with no persistence; some mammalian carnivores, primates, and birds of the family Corvidae show spontaneous and active search behavior in response to the disappearance of an object. This third group's performance corresponds to at least Stage IV of Piaget's ranking of object permanence performance.

When considering the current literature on A-not-B errors in nonhuman animals, it has to be taken into account that the task set-up often varies from Piaget's original one. Most studies use variations of Uzgiris and Hunt's (1989) sequence of tests where the task for successive visible displacement involves the hiding of the target (treat or toy) out of sight in one location before it is moved by the experimenter in plain sight to a second location. In the original tests by Piaget,

the target was hidden and retrieved from location A several times before it is hidden in location B for another retrieval. A third, combined set-up was used by Amici et al. (2008). They hid the target in location A three times, then in the fourth trial they visibly moved it to location B after first hiding it at A. Zucca et al. (2007) repeated the hiding in location A twice before visibly hiding the target in location B. Most other current studies omit the repeating stage, such as Deppe et al. (2009) in their study with lemurs. These rather substantial differences in methodology need to be taken into account when considering and comparing findings. The method without the repeated retrieval excludes the explanation that the error is caused by motor memory. But it needs to be studied further whether errors in the visible displacement task with no repetition involve the same cognitive processes as the A-not-B error as initially investigated. Some authors suggest that social factors could explain the preference for the A location in certain species (Topál et al. 2008). Because the experimenter points to the location, interacts with it, and thereby teaches the animal where to look, it tends to focus on this location, instead of searching for the target independently. As seen in the history of animal cognition (Clever Hans – Pfungst 1911), every human involvement in an experiment can affect the outcome, especially in domesticated species such as dogs. This needs to be taken into account when designing and interpreting experiments, even if it does not apply to all species. Kis et al. (2012), for example, found that the “teaching” factor does not apply to common marmosets (*Callithrix jacchus*).

Table 1 provides a sample of studies across a range of species. For an overview of recent studies, see Cacchione and Rakoczy (2017).

Many species tested show the A-not-B error during their early development, but not when they are adults. Their developmental cognitive changes follow the same path as those of humans. The only exception so far are domestic dogs (*Canis lupus familiaris*) and cats (*Felis catus*). Neither puppies (Gagnon and Doré 1994) nor kittens show the perseveration error (Dumas and Dore 1991) whereas adult cats do (Dumas and Doré 1989). For adult dogs, the results are inconclusive as

different set-ups have been used in different studies. The specific methodology of each study must be taken into account before any comparisons between species can be made.

### Spatial A-Not-B Errors

The A-not-B error involves the perseveration of a movement toward one location, and the inability to switch the movement away from it, despite the fact that the target was obviously moved toward a new location. The testing set-up for infants usually requires reaching for the target. But this behavior can also been seen on a larger scale, in detour tasks. The perseveration error occurs when participants attempt to use a previous route around a barrier despite a visible change in the correct path, thus rendering the attempted route impossible (McKenzie and Bigelow 1986). The basic set-up has the participant facing a straight barrier and they have to move around it through a gap at one end toward a target on the other side. The gap to walk through is in location A. After a few repeats, the barrier is moved so that the gap is now in location B, the other end of the barrier. There is no change in the size of the gap, or the difficulty in the task, only a change in location. This spatial set-up removes the experimenter input of touching or

indicating the target locations and therefore excludes social explanations for any errors. Perseveration cannot be explained by simple motor memory, as the detours take several seconds and involve far more complex movements than simple reaching, as in the original task. McKenzie and Bigelow (1986) explored this detour behavior in human infants and found the spatial equivalent of the A-not-B error in young infants (10-months old), but not in 14-month-old children. This indicates that the same cognitive development applies to both the searching and the detour behavior.

Several studies have shown that dogs will follow a previously learned path even if this no longer leads directly to the goal. Buytendijk and Fischel (1932) were the first to describe how dogs persevere with a detour path, even after changes in the set-up would make an alternative path much faster and easier. Clarke et al. (1951) found that 10-month-old puppies showed perseveration errors in detour tasks. Puppies persisted in following the wrong, but previously learned paths even if this resulted in falling from the end of a false ramp in an elevated detour test. These findings were confirmed for adult dogs reared in restricted environments by Thompson (1954).

More recently, the spatial A-not-B error has been explored in dogs (Osthaus et al. 2010) as well as horses, mules, and donkeys (Osthaus et al.

2013). The number of repetitions of the A trial varied and therefore allowed an exploration of the influence of repetition on perseveration. Unlike in the search set-up, adult dogs persevere in the detour task, even after one A trial. Horses perform comparably, whereas mules and donkeys had lower rates of spatial perseveration and showed fewer A-not-B errors. So far, equines have not yet been tested for A-not-B errors involving the search set-up. Further tests show the same error in cats, chickens, and sheep (Osthaus, unpublished data).

## Summary

The A-not-B reaching error has been shown to exist in most nonhuman species tested so far (Table 1). There are a few exceptions: apes (apart from orangutans), puppies, kittens, wolves, and goats. It must be taken into account that, although there is growing number of studies investigating object permanence in a wide range of species, most of them do not use specific tests to investigate the A-not-B error. In addition, the methodologies vary immensely between studies. Although many studies use the basic set of tests by Uzgiris and Hunt (1989) that explore successive visible displacements, the precise set-up varies between studies and makes comparisons near impossible. It is therefore difficult to compare species with regard to the A-not-B error until a standard test with a defined number of repetitions and movements between targets is implemented.

## Conclusion

The A-not-B error is a behavior observed across the animal kingdom and its causes remain undiscovered to date. Only with standardized tests will it be possible to investigate and identify the underlying cognitive processes.

## Anthony (Tony) A. Wright

Jeffrey S. Katz

Department of Psychology, Auburn University,  
Auburn, AL, USA

Anthony A. Wright was born in Los Angeles, California, on January 4, 1943. Wright was raised in Glendora, a small bedroom community Southeast of Los Angeles founded by Wright’s paternal great grandfather. Wright’s father, Carlton Wright, continued the family tradition of being a Southern California citrus grower. Wright’s mother, Judith Wright, was an elementary school principal in the neighboring town of Covina. Wright spent much of his youth along the coast, surfing, sailing, and developing an affinity for fast cars. In 1965, Wright received a BA in Psychology from Stanford University (where he met his soon to be wife, Susan Briggs Wright). While at Stanford, Wright was greatly influenced by Gordon Bower, Richard Atkinson, Ernest Hilgard, and Karl Pribram. In 1970 he received an MA and in 1971 a PhD in Experimental Psychology both from Columbia University under the mentorship of Bill Cumming and Tony Nevin. Wright moved to Texas as an assistant professor at the University of Texas at Austin and was close to Janet Spence and Abe Amsel. From 1972 to 1994, he was a

faculty member in the Sensory Science Center of the University of Texas Health Science Center at Houston and since has been a professor in the Department of Neurobiology and Anatomy at the University of Texas McGovern Medical School at Houston.

The hallmark of Wright's research has been discovering functional relationships in comparative cognition. Functional relationships are revealed when one variable (independent) is manipulated along a continuum and its influence on another variable (dependent) is determined. This research strategy is at the core of Wright's major contributions to the study of animal cognition and behavior and began with his dissertation research. Wright's dissertation, "Psychometric and psychophysical hue discrimination functions for the pigeon," revealed hue-discrimination functions for pigeons via parametric manipulation and signal-detection theory analyses of small wavelength differences across the pigeon's visible spectrum and related these color discriminations to the pigeon's color categories derived from matching-to-sample color-naming functions. Following his contribution to color perception (Wright 1972; Wright and Cumming 1971), Wright began to focus on memory processing. Wright developed the first visual list memory procedures for nonhuman primates (Sands and Wright 1982). The defining feature of the visual list memory work was a recency-to-primacy shift in the serial position function as the delay increased between the presentation of a list of items and the probe (test) item. This functional relationship in the list-memory function over delay was discovered in all species tested: capuchin monkeys, rhesus monkeys, humans, and pigeons. These functions represented a qualitative similarity in memory processes across species and have been instrumental to understanding proactive and retroactive interference in nonhumans and humans (Wright 1998; Wright et al. 1985). More recently, Wright's interest in memory processes has focused on visual short-term memory. Wright developed a variant of the popular change detection procedure used with humans for nonhumans (Wright et al. 2010). By parametrically manipulating the number of items to be

discriminated, Wright has shown that like human memory, nonhuman memory functions are accounted for by the same variable-resource model of memory (e.g., Devkar et al. 2015). Wright has also made major contributions to abstract-concept learning in nonhumans. He challenged claims that nonhumans could not learn abstract concepts based on "failures to find." Wright has shown that a variety of species can learn abstract concepts if the conditions are right. As one example, he has shown that the training set size is critical to revealing clear evidence for abstract concepts. By systematically varying training set size, Wright has shown that abstract-concept learning increases with training set size until full concept learning occurs in all species tested (capuchin monkeys, rhesus monkeys, black-billed magpies, Clark's nutcrackers, and pigeons). Discovering the functional relationship between set size and accuracy revealed these species share the same qualitative ability to learn abstract concepts (Wright and Katz 2006; Wright et al. 2017).

Wright's passion for designing an apparatus has also been at the center of his research. He is a self-taught carpenter and machinist. He is driven by determining the best environment to test an animal while maintaining rigorous experimental control. As one example, he developed an operant chamber where pigeons peck at stimuli on the floor of the operant chamber, as opposed to the side of a wall (as seen in traditional chambers). Wright has also been a charismatic teacher at the UT Medical School for Medical Neuroscience and Problem-Based Learning. Inside and outside the laboratory, Wright was and remains a mentor to many of today's leading comparative psychologists. In 2012 the Comparative Cognition Society honored Wright with a special symposium and a series of articles, further showing his impact on animal cognition and behavior. These articles were published in *Behavioural Processes* along with Wright's retrospective feature article (Wright 2013).

## Anthropomorphism

Gordon M. Burghardt

University of Tennessee, Knoxville, TN, USA

Anthropomorphism has for most of the last century been considered a grievous sin in the study of animal behavior. Simply put, anthropomorphism is the attribution of human characteristics to non-human entities. It is often erroneously applied only to other animals using terms in describing and interpreting their behavior that derive from human psychology and behavior. Originally, however, it was applied by theologians and philosophers to viewing gods and other supernatural entities as possessing human-like emotions, thoughts, and motivations along with additional supernatural capabilities. The famous painting by Michelangelo in the Sistine Chapel of a white-haired Caucasian grandfather figure touching Adam epitomizes this approach, along with claims that God is jealous, gets angry, loves us as a parent, and so on. While many philosophers and theologians opposed such attributions to spiritual beings, their admonitions hold little sway with most religious people who want a personal god who will respond to them in psychologically familiar ways. Interestingly, the Judeo-Christian bible supports such anthropomorphism about both God and nonhuman animals (ants are industrious, snakes are both wise and vile, doves are innocent, etc.). This anthropomorphism is widespread in Hinduism, Judaism, Shinto, Norse, Greek, Roman, Australian aborigine, and many tribal religions. Supernatural agents have varying amounts of human attributes, famously enshrined in the Christian belief that Jesus was simultaneously divine and human. Furthermore, animals have themselves been models for numerous deities.

Outside of overtly religious sources, Aesop's fables and even the early compendia by Aristotle and Pliny from ancient Greece and Rome have numerous anthropomorphic descriptions. In many of these early writings, as well as folklore around the world, animals were used to provide moral lessons for humans. Pre-Darwinian writings by

early naturalists tried to be more careful, but often failed. An encyclopedic treatment mixed fine observations with human associations in sections with titles such as sympathy, joy, pain, envy, cruelty, jealousy, anger, revenge, hatred, gratitude, and generosity (Thompson 1851). Darwin's books comparing human and animal behavior (Darwin 1871, 1872) frequently used anthropomorphic attributions of animal mentality and emotion to support claims that rudiments of what we feel most distinctive about the human mind can be found in other species. Evolutionary approaches to mind and behavior have a long history of being similarly criticized for being too readily liable to seeing human attributes of thoughts, feelings, and emotions in nonhuman animals. For example, Romanes, Darwin's protégé on behavior, often resorted to anecdotes and anthropomorphic attributions (Romanes 1892) that we are quick to ridicule today as counter to good science (Galef 1996). For example, Galef wrote (p. 8) that "introspection, anecdote, and anthropomorphism all interfered with development of animal behavior as a scientific enterprise. Each had to be purged from discussions of animal behavior before the field could emerge as a science."

As scientists continue to look for the human in the "animal" and "animal nature" in much of our own behavior, emotions, and thought processes, it is difficult to come up with ways of talking that avoid anthropomorphic elements. Attempts to come up with completely behavioristic terminology have proved generally fruitless, even among their adherents, and thus the turn to cognitive approaches to mental processes that stray from mere behavioral descriptions. This is, however, more than a return to "folk psychology" and represents attempts to understand how cognitive and emotional mechanisms compare across taxa, including the human and nonhuman. The discussion of theology alongside ethology and comparative psychology is deliberate, as much discussion of animal behavior is actually motivated, although often unstated, by attempts to gain insights into human behavior and mental life and their evolution. That is, many are interested in the lessons we might learn from our evolutionary connections with other species involving decision making,

learning, culture, language, morality, ethics, how we treat other animals, and our obligations to the biosphere (Bekoff 1998; Griffin 1976). Indeed, a major reason for the modern reengagement with psychological similarities and differences across species were the critiques by animal rights and welfare movements that questioned many of our traditional ways of treating animals on farms, in laboratories, as pets, in zoo and aquariums, and even in the wild, such as hunting, fishing, and game and pest management practices. Thus, while vocal critics label much current animal behavior research as still unacceptably anthropomorphic (Wynne 2007), the need to develop useful and scientific ways of comparing psychological processes across species remains. Moreover, it must not be forgotten that many of the claims of early writers, albeit based on incomplete data and premature attributions of complex abilities to animals, have often been shown to be rather prescient (Burghardt 1985; Romanes 1883). While current discussions on inferences into the mental lives of other species utilize more accurate scientific methods and findings, behaviorist critiques are still ongoing, as seen in the views of Wynne and others, although these have been countered (Burghardt 2004, 2007). In large part the critics' main concern is that an unbridled mentalism has reemerged in animal behavior and psychology in general that has been abetted by relaxing the opposition to mentalistic approaches that marked both behaviorism and Tinbergen style ethology (Wynne 2007).

Although a thorough history of anthropomorphism in the study of animal behavior is not appropriate here, what is the status of anthropomorphism in animal behavior studies today? Probably the best source for accessing the literature on anthropomorphism is a book that brings together many authors and approaches to anthropomorphism (Mitchell et al. 1997). A treatment of all the often overlapping labels used for distinguishing "good" and "bad" anthropomorphism would be far too lengthy, but terms such as the following may be encountered. Listed in alphabetical order these include applied anthropomorphism, categorical anthropomorphism, critical anthropomorphism, folk psychology, generic anthropomorphism, global

anthropomorphism, heterophenomenology, inaccurate anthropomorphism, intentional stance, mental state attribution, mock anthropomorphism, neural analogical inference, phenomenological empathy, pragmatic anthropomorphism, reflective anthropomorphism, reflective ethology, situational anthropomorphism, subjective analogical inference, and subjective anthropomorphism. While the different subtypes of anthropomorphism and the labels used are often confusing, Robert Mitchell provides a pathway through the diversity (Mitchell 1997). Here I review a path that I have found useful.

Frans de Waal, who wrote the foreword to the Mitchell et al. (1997) volume, has revisited the field of comparative cognition and cognitive ethology in a historically situated and personal treatment that is both informative and interesting for students, general readers, and professionals alike (de Waal 2016). He criticizes not only the widespread anthropocentrism found in psychology and the social sciences and humanities, but argues that *anthropodenial*, a term he had coined, is often deployed as uncritically as is anthropomorphism. He deploys many examples on a diverse range of topics to argue that most researchers today in the field of comparative cognition are not equating human and animal mental states, emotions, or cognitive processes so much as to trying to establish the extent of the similarities and differences through empirical studies. Recent writers other than de Waal and primatologists have been at pains to argue that in studies of moral behavior to perceptual processes in non-human animals, we need to evaluate the abilities of other species on their own terms (Bekoff and Pierce 2009; Rivas and Burghardt 2002) a lesson going back to Jakob von Uexküll (1909), but still often forgotten in the world of anthropodenial (de Waal 2016). Indeed, studiously trying to avoid anthropomorphism can actually result in what can be termed *anthropomorphism by omission* (Rivas and Burghardt 2002).

Anthropomorphic descriptions are ubiquitous in our lives. We make inferences about the thoughts, emotions, and feelings, of other humans, even though, just like with animals, we have no direct conduit into their mental or personal worlds. Indeed, if we did not do this, normal

social life and interactions would be impossible. That we also make inferences about other animals is not surprising at all, as it has helped us in our dealings with domesticated and wild animals, even if errors are frequent and often dangerous, as when the behavior of strange dogs and wild bears is misinterpreted. We also extend our anthropomorphic reach to inanimate things, such as the weather, symbols, and animated movies. Anthropomorphism allows us to get deep pleasure from novels, plays, and poetry. Even young infants can interpret the actions of simple geometric objects moralistically (Bloom 2013). Radical behaviorists rarely describe the behavior of their pets, children, or colleagues without anthropomorphic language, and they would be viewed rather weirdly if they did. It is not just that professional jargon and daily language often differ, but that deeper issues are involved. An approach that works with and uses our anthropomorphic tendencies seems more useful than one of blanket denial. A way of doing this is *critical anthropomorphism*, which accepts that we are rather adept at making inferences about the mental lives and experiences of others based on our own experiences, experiences shaped by our evolutionary history that shares many recurrent life history demands with other species (Burghardt 1985, 1991). Given this, we can hypothesize how other species, as well as conspecifics, interact with their environment and experience events; but this must be based on using all the scientific information about the other species at our disposal such as their natural history, social system, sensory abilities, neural mechanisms, physiology, prior experiences, and so forth. Detailed explications of critical anthropomorphism are available (Burghardt 1991, 1998), but the main lesson seems to be that we should not ignore our own mental lives as we try to scientifically explore the behavior of other species and how they process their “private” experiences.

## Antipostatic Selection

### ► Frequency-Dependent Selection

## Anticipation of Future Events

Thomas Suddendorf and Jonathan Redshaw  
Centre for Psychology and Evolution, School of Psychology, University of Queensland, St. Lucia, QLD, Australia

## Introduction

Humans routinely anticipate future events and organize current actions accordingly. This capacity has been termed “episodic foresight” (Suddendorf and Moore 2011) and is fundamental to enabling humans to control the future by planning, preparing for, and shaping events in desired ways. Adult humans tend to think more about the future than the past and even when thinking about past events, it is often done with a view toward influencing future outcomes (e.g., Baird et al. 2011; Baumeister et al. 2016). The human capacity to anticipate events has been argued to be unrivalled by any other animal species and considered a key adaptive strategy responsible for humans’ dominance on the planet (Gilbert and Wilson 2007; Suddendorf and Corballis 1997).

However, even if there is something uniquely human about episodic foresight, this is not to say that other species do not have sophisticated future-directed cognitive capacities. In fact, the

claim about human uniqueness has triggered a wealth of recent research on the prospective competences of other animals. From research on navigation to preparation, and from experimental studies on tool use to studies on choices with future consequences, this is now an extensive field in comparative psychology. Below recent findings from this domain are reviewed.

The future matters. In many situations, animals would benefit from some kind of capacity to anticipate significant potential future events. It is perhaps not surprising, then, that many species do indeed use cues to anticipate arising threats and opportunities. For instance, animals may take advantage of signs that predict future availability of resources, and those that do this more effectively than their competitors have a selective advantage (Alcaro and Panksepp 2011). Similarly, animals that can predict the approach of a threat can increase their chances of avoiding harm by taking pre-emptive action. These pressures have led to the evolution of quite sophisticated cognitive and perceptual strategies. For example, if chickens see a moving shadow on the ground, they tend to scan the sky in apparent search for a potential danger, such as a raptor. If they detect such a predator, they rapidly try to avoid falling prey, and their visual system links shadow and raptor to facilitate this process (Wilson and Lindstrom 2011). More generally, given that predator and prey species do not just fight, but also are in an evolutionary arms race pitting attack mechanisms and early warning mechanisms, there should be considerable selection pressure toward capacities to anticipate future events. The better a species can use cues to predict an opportunity or threat, the greater the chance to enhance fitness, for instance, through increased vigilance or appropriate approach or avoidance behavior (Bateson et al. 2011; Nettle and Bateson 2012). So, let us start with research on how animals learn to move toward potential positive and away from potential negative events.

## Spatial Cognition and the Future

There is a wealth of research documenting remarkable navigation capacities in diverse

species. For instance, animals such as rats (Tolman 1948) and bees (Menzel and Greggers 2015) construct something like a cognitive map to move efficiently through their environment. This allows them to increase their chance of escape in the face of a threat and their chance of obtaining the resources they need. Some monkeys, such as mantled howlers, for example, travel long distances in ways that seem to enhance the quantity of mature fruits they can consume (Hopkins 2016).

The neurocognitive basis of mammalian navigation likely involves fundamental homologies. In particular, the hippocampus has been identified as the neuronal foundation of cognitive maps (O'Keefe and Nadel 1978). Specific cells in the hippocampus respond to specific places in the environment. These place cells are part of a complex network of cells coding representations of space such as grid cells, border cells, and head-direction cells (Moser et al. 2015). The hippocampus is thus critical to representations of space and its affordances that enable a mammal to flexibly plot paths to reach a target even when confronted with novel obstacles.

Recent single cell recording in rats suggests that place cells in the hippocampus fire in particular sequences that can be reactivated at a later point, possibly indicating a mental replay of the past movement (Buhry et al. 2011). Such sequences have also been recorded prior to a rat taking a path, potentially indicating planning of the movement required to reach a goal (Dragoi and Tonegawa 2011; Gupta et al. 2010; Heyman 2007; Pfeiffer and Foster 2013). Unfortunately, it has remained uncertain how exactly such neural activation patterns relate to mental experience and foresight (Balter 2013). Indeed, it is not even entirely clear what, if anything, the function of these patterns are (Azizi et al. 2013; Bendor and Spiers 2016; Silva et al. 2015). Nonetheless, in the light of the established behavioral evidence indicating navigational competences, and given that the hippocampus is also critical to human episodic memory and foresight (Addis et al. 2007), it may seem likely that they do play a significant role.

Various research suggests that humans' closest surviving animal relatives have considerable route

planning capacities (Boesch and Boesch 1984). It has even been argued that adult male orangutans let others know where they are going to go next by emitting long calls in that direction (van Schaik et al. 2013), though it is difficult to disentangle any such intention from the leaner explanation that they tend to face both in the direction they are heading and in the direction they are calling. Common chimpanzees have been argued to strategically build nests to ensure that a desirable breakfast option is nearby (Janmaat et al. 2016), though again it is difficult to rule out alternative interpretations involving innate predispositions and/or associative learning. Behavioral tendencies that somehow result in future fitness benefits are common but they need not necessarily rely on explicit planning and intentions about future events (Suddendorf and Corballis 2007). Even bacteria demonstrate preparation ahead of arriving at a different environment. When *E. coli* travel through human digestive tracts, they switch on genes for maltose digestion even before reaching the maltose-rich regions (Mitchell et al. 2009). Natural selection can bring about such future-directed patterns when there are regularities the organisms encounter over many generations. Debate about what navigation and the neurological system underlying it tells us about animals' capacity to anticipate future events has thus continued (Corballis 2013a, b; Suddendorf 2013b). Next we turn to experimental behavioral studies that examine animals' capacity to take future consequences into account.

## Prudent Choices

A common way to examine choices that have distinct temporal consequences are paradigms in which subjects must pick one of the two options, often contrasting an immediate small reward and a larger reward that becomes available only after some time has passed. In these intertemporal choice tasks, animals and humans tend to lean toward selection of the immediate rewards, but in certain circumstances will pick the delayed option, such as when the reward on offer is very attractive and when the delay is quite short

(Cheke et al. 2011). Species differences have been reported in such paradigms. For example, pigeons and rats may pick delayed larger rewards when the delay is only a few seconds (Tobin and Logue 1994), but monkeys and apes sometimes pick larger rewards that entail waiting for over a minute (Rosati et al. 2007; Santos and Rosati 2015).

Chimpanzees appear to be particularly capable to delay. In one version of these tasks in which a small reward had to be kept for some time before it could be exchanged for a 40 times larger reward, chimpanzees even waited for up to 8 min (Dufour et al. 2007). In another paradigm involving gradual accumulation of small rewards, chimpanzees also postponed consumption for several minutes (Beran 2002; Beran and Evans 2006), and even appeared to deploy self-distraction while they waited (Beran et al. 2014; Evans and Beran 2007).

Although these tasks all seem to measure some capacity for prudent intertemporal choice, there is some concern that other factors may influence decision making. Indeed, there are various simple decision rules that could drive these choices even without anticipation of future events (Stevens 2011). In a selection task, for instance, an individual may simply approach the more attractive reward without any consideration of the entailed delay, turning the apparent intertemporal choice simply into a preference. One major recent critique of these paradigms has been that they typically involve many training and testing trials, and little consideration of the period of time between individual trials. If a choice of an immediate smaller reward shortens the time before the next trial, then it may well be most beneficial to continue choosing immediate rewards. When the salience of the intertrial delays is manipulated, the choices of animals change in accordance with this principle (Blanchard et al. 2013; Pearson et al. 2010).

Nonetheless, there is considerable consistency in the results to indicate animals such as rats, dogs, pigeons, and apes can choose to obtain a larger reward if it involves delaying gratification for relatively short periods of time (Anderson et al. 2010; Evans and Beran 2007; Leonardi et al. 2012; Osvath and Osvath 2008; Reynolds et al. 2002; Stevens et al. 2011). In some studies,

humans display similar response patterns when the rewards are foods (Rosati et al. 2007) and drinks (Jimura et al. 2009). However, this observation should not distract from the fact that in contrast to the evidence from nonhuman animals, humans frequently choose to put immediate gratification to one side to pursue rewards that are days or even years in the future. In fact, humans often deliberately manage and weigh their options by assessing the desirability and likelihoods of multiple possibilities. There are usually more than two options and more uncertain contingencies – both known and unknown – affecting a future outcome than is examined in intertemporal choice paradigms (Fawcett et al. 2012). Furthermore, it is not always delaying that is the most prudent option. Humans may choose to seek immediate gratification in one context, for instance where the likelihood of a better future payoff is judged insufficient, and choose to delay in others (Bulley et al. 2016). Little is known about animal capacities to make flexible choices between more than two options, and involving different probabilities and objectives.

Indeed, it is not even clear if nonhuman animals appreciate the basic fact that the future is uncertain and that it is often prudent to prepare for more than just one possible outcome of a future event. A simple paradigm developed to examine such a capacity involved dropping a desirable target into an upside down Y-shaped tube and giving subjects an opportunity to catch it (Redshaw and Suddendorf 2016). Two-year-old human children prepared for the drop by placing a hand under only one of the potential exits, and thus ended up missing out on the reward on half of the trials. Older children were increasingly more likely to prepare for both possibilities, with most 4-year olds spontaneously covering the two tube exits from trial one onward. By this age, then, children can consistently prepare for at least two mutually exclusive versions of an immediate future event. Some of the younger children eventually covered two exits but then subsequently regressed to covering one exit, implying a lack of insight into the uncertain nature of the future outcome. Interestingly, chimpanzees and

orangutans that were given this task performed similar to the youngest children, suggesting that they may not be capable of preparing for mutually exclusive events (also see Suddendorf et al. 2017). However, this is only an initial indication and replications with more animals are needed.

## Preparation

Humans can imagine any number of events and diverse outcomes – and prepare accordingly. Even in the absence of any present indicators of these potential futures, we can mentally entertain possibilities and practice responses. When we plan a holiday, for instance, we can ponder the anticipated pleasures and potential problems we may encounter. These thoughts, rather than external cues, may then prompt us to prepare for certain options (e.g., take the scuba license) and potential hazards (e.g., pack the seasick tablets). Though this may primarily reflect absence of evidence rather than evidence of absence, to our knowledge there is no indication that other animals engage in such deliberate preparations in the absence of external cues (Miloyan et al. 2015).

In the same vein, humans can prepare not only for anticipated external circumstances, but also for changes in their own internal states. Without being thirsty or cold in the present moment, we may set out to secure drinks and a way to keep warm at a later stage. The Bischof-Köhler hypothesis states that this capacity to imagine future motivational states, even when they conflict with one's current motivational state, is uniquely human (Bischof 1985; Bischof-Köhler 1985; Suddendorf and Corballis 1997). Other animals do, of course, act in ways that secure future needs, such as when they cache food or build a nest, but this need not necessarily be done with the future situation in mind (e.g., consider a young squirrel that stores nuts without ever having experienced winter). Nonetheless, this hypothesis has been challenged. For instance, two squirrel monkeys were argued to have anticipated their future thirst when they began to gradually prefer one piece of thirst-inducing date that was followed by water

delivered half an hour later, over the option of four pieces with water available only after 3 h (Naqshbandi and Roberts 2006; but also see Paxton and Hampton 2009). However, one may wonder why the monkeys, if they really were thinking about their future thirst, did not simply select the four pieces and wait until water was available before eating them (Suddendorf and Corballis 2010).

Other studies have exploited the fact that animals can lose their appetite for one particular food in comparison to other foods. Jays that were first fed to satiation with one type of food and then given the chance to cache either this same food or a different type seemed to store the currently undesirable food that would become desirable again in the future (Cheke and Clayton 2012; Correia et al. 2007). However, there are reasons to be cautious about a rich interpretation of these data (Suddendorf and Corballis 2008), for instance, because the behavior may reflect a cued present motivational state that incidentally happens to be no different from the future desire state (Redshaw 2014).

A common chimpanzee at a Zoo in Sweden has displayed an unusual behavior that has been claimed to run counter to Bischof-Köhler hypothesis. He placed stones and bits of concrete into piles and later used these as ammunition to hurl at zoo visitors (Osvath 2009; Osvath and Karvonen 2012). Because the piling up of the hard objects occurred in a calm state, it was argued that the chimpanzee may have anticipated and prepared for his need to hurl things as part of his excited display. Though there was a recent report of chimpanzees tossing stones into a tree cavity (Kühl et al. 2016), such preparation behavior has not been reported from other zoos nor in the wild. Experiments are needed to determine what has been driving this curious behavior and whether the chimpanzee displays other signs of foresight (Suddendorf 2013a).

Most experiments on preparation have given apes the opportunity to secure a tool for a future use. In one study, bonobos and orangutans were trained to obtain food with a tool and could then take that tool or distractor items out of the room

(Mulcahy and Call 2006). Perhaps unsurprisingly, the apes preferentially took the tool that was strongly associated with reward. More interestingly, on about half the trials they took the tool back into the testing room when given access an hour later and used it to obtain more of the reward. One bonobo and one orangutan, when the task was presented in the evening, even returned with the tool the next morning. In a similar study involving forced choices, three apes even showed preference for the target tool that was associated with a large reward, when one of the distractor options was an instant small food reward; they also showed a preference for novel tools that were similar in shape and function to previous tools that had solved the task (Osvath and Osvath 2008). However, both these studies have attracted methodological criticisms and systematic replications that rule out potential alternative explanations remain desirable (Redshaw 2014; Suddendorf 2006; Suddendorf and Corballis 2008). Furthermore, even if apes are capable of solving these tasks with some foresight, there is as yet no evidence to suggest that they can do so without first being cued by the immediate presence of the problem or the tool (Redshaw 2014).

One recent study examined great apes' capacity to prepare for multiple problems (Bräuer and Call 2015). By preparing several of the same tools, subjects could obtain a number of rewards. After they had learned to bite off and insert a piece of wood into a tube to get a reward, the experiments blocked access to the food apparatus and showed them how either none, one, or eight tubes were baited. The apes then had the opportunity to prepare before they were given an opportunity to gain the rewards. They made tools more often when rewards were available than when they were not, and they made more if there were eight rather than one reward available. So, this indicates some capacity for relevant preparation. However, instead of making eight tools to secure all rewards, they prepared less than two tools on average. So, the preparation was far from optimal, even though the apes had full visual access to the future problem during the tool preparation phase. It remains to be seen whether they would show a differential

performance across conditions if visual access were blocked and the future rewards had to be represented in working memory.

Another simple recent preparation task involved a series of paddles that subjects could turn so that a reward would fall where it could be retrieved. Bonobos and orangutans were able to rotate the paddles to direct the reward toward an open exit, but did poorly when a paddle below the paddle holding the reward had to be turned first so as to avoid the reward falling the wrong way (Tecwyn et al. 2013). Yet, in early studies, great apes could learn to work backward from a goal and select an appropriate initial choice – at least after extensive training and while the final reward was visible (Döhl 1968; Rensch and Döhl 1968).

In studies in which apes could not see the reward, performance was poor (Dufour and Sterck 2008). After having been trained that returning a token leads to a food reward, chimpanzees were given the opportunity to collect tokens or other objects and to bring them an hour later to a room in which they could exchange them for food rewards. The apes showed no sign of planning for the future exchange: they only rarely brought tokens and obtained rewards, and did not preferentially take tokens over distractors. In a similar study, three apes did show some preferential exchange of previously reinforced tokens, but unlike the previous study, the distractor items were not associated with food and so simple associative explanations cannot entirely be ruled out (Osvath and Persson 2013). Similarly, a study that reported some capacity to transport and exchange tokens in bonobos and orangutans is difficult to interpret as it did not involve any distractors (Bourjade et al. 2014). The results of these token-exchange paradigms indicate that some apes can select and transport relevant objects, but it remains possible that they may only do so because of learned associations with past rewards, and not because they have anticipated the specific future exchange events (Redshaw and Bulley 2017).

On a final note, there is as yet no evidence that any nonhuman animals can reflect on the *limits* of their prediction capacities and prepare

accordingly. Humans can prepare for multiple possible outcome of a single future event (cf. Redshaw and Suddendorf 2016) and may make complex contingency plans. Humans even predict their own future failure to remember and may prepare for that by creating alerts, writing lists, or leaving items in conspicuous locations (Risko and Gilbert 2016). Although a similar function can be observed in, for instance, the behavior of ants when they leave pheromone trails (Sterelny 2003), there is as yet no sign that animals flexibly anticipate their own prediction problems and therefore deploy reminders. However, this may reflect absence of evidence rather than evidence of absence. Future research might want to address this by, for example, presenting apes with search tasks in which they are given opportunities to mark relevant locations for future rewards.

## Conclusion

Although recent studies on navigation, choice, and preparation indicate some future-directed competences in nonhuman species, and therefore demonstrate some continuity in cognitive evolution, the complexity and flexibility of human foresight seems unrivalled. Furthermore, many of the described behaviors can be interpreted not only in a rich manner that attributes foresight, but also in leaner ways. The problem is that actions can be beneficial for one's future even when one was not aware of such contingencies. In other words, it is difficult to establish that an animal acted with the future in mind. How can we rule out associative learning, instincts, or mere chance as alternative explanations? Some quite conservative behavioral criteria have been proposed (Suddendorf and Corballis 2010): "(1) use of single trials to avoid repeated exposure to the same stimulus-responses relationships; (2) use of novel problems to avoid relevant learning histories; (3) use of different temporal/spatial contexts for the critical future-directed action to avoid cuing; (4) use of problems from different domains to avoid specific behavioral predispositions." Human children

demonstrate competence in tasks that meet these criteria relatively late, around age 4 (Redshaw and Suddendorf 2013; Suddendorf et al. 2011) at an age when purported critical mental component capacities, such as an ability to metarepresent, emerge (Suddendorf and Redshaw 2013). At present, there is no comparable evidence from non-human animals that meet these stringent criteria. But the future is uncertain – and it remains possible that future research may demonstrate more sophisticated animal capacities to anticipate future events.

## Ape Cognition and Conservation Initiative (ACCI)

Amanda J. Epping<sup>1</sup> and Jared P. Taglialatela<sup>1,2</sup>

<sup>1</sup>Ape Cognition and Conservation Initiative,  
Des Moines, IA, USA

<sup>2</sup>Kennesaw State University,  
Kennesaw, GA, USA

### Definition

The Ape Cognition and Conservation Initiative (Ape Initiative) is the only dedicated research facility in North America to house and study bonobos. In a new era of great ape cognition and behavioral research, Ape Initiative is an international scientific destination with a focus on science, conservation, and civic engagement.

### Mission and Vision

The Ape Cognition and Conservation Initiative is dedicated to the conservation and protection of great apes worldwide, as well as responsible and sustainable research aimed at uncovering the evolutionary origins of human language, cognition, and behavior. The Ape Initiative aims to use the knowledge we gain from studies with great apes to better humanity by increasing public knowledge and understanding of our own species' origins, as well as our connection with the natural world. With a three-tiered mission of science, conservation, and civic engagement, the Ape Initiative aspires to become the leader in ape cognition research and conservation education.

### Science

Under the direction of Jared Taglialatela, PhD, and William Hopkins, PhD, the Ape Initiative's programs aim to enrich the lives of the bonobos and increase our understanding of great apes worldwide. By using lexigram keyboards to communicate with their caregivers, the bonobos are not only active participants in their own care, but are able to provide unprecedented insight into the mind of the species most closely related to humans.

### Conservation

The Ape Initiative continues to develop programmatic relationships with universities locally and globally to provide research and educational opportunities such as training programs in the behavioral sciences and internship programs for veterinary medicine. In time, the Ape Initiative hopes to train a new generation of scientists who can continue to learn from the apes in our care and increase our understanding of the evolutionary origins of our own species. It is the Ape Initiative's contention that understanding the behavior, ecology, and cognition of great apes is synonymous with conserving them.

### Civic Engagement

The Ape Initiative is a valuable resource for schools and organizations that share in the mission to educate individuals of all ages. One of the long-term goals of the Ape Initiative is to promote scientific literacy, conservation education, and environmental stewardship in the local community and beyond. The Ape Initiative works closely with educators to provide the facility and unique population of apes as a resource to supplement and expand existing primary and secondary school STEM initiatives.

The vision of the Ape Initiative is to be an internationally recognized research facility for the study of ape cognition and communication. Prior to the founding of the Ape Cognition and Conservation Initiative, the five bonobos were the responsibility of the Great Ape Trust where the focus moved away from serious scientific inquiry and the associated public and private sector

support for research. Since Hopkins and Taglialatela formed the Ape Initiative in December of 2013, the focus has been redirected to develop a comprehensive research program. This effort includes both a rigorous and sustained effort to secure programmatic funding from major governmental agencies and private foundations to support scientific research and the dissemination of the results of this research to the public by publishing these findings in high-impact, peer-reviewed journals.

## History

The bonobo ape-language project followed the LANA (Language Analogue) project, pioneered by Duane Rumbaugh and Ernst von Glasersfeld in 1971 at the Yerkes National Primate Research Center and later the Georgia State University Language Research Center in Atlanta, Georgia. A young female chimpanzee, Lana, was taught to communicate with researchers on a computerized keyboard using visual-graphic symbols, or lexigrams, created using simple grammatical structure (Rumbaugh 1977). Bonobos were included in the research in 1980 with the addition of Matata, a wild-born female. Matata did not successfully learn to communicate via lexigrams despite considerable formal instruction, but her adopted son, Kanzi, spontaneously began to not only use and understand these visual symbols to communicate with researchers but also acquired an advanced level of spoken English comprehension, through observation and exposure during his mother's training sessions (Savage-Rumbaugh et al. 1993).

In 2005, the project moved to Des Moines, IA, to a state-of-the-art custom-built facility with support provided by a single donor, a local philanthropist, Ted Townsend. Unfortunately, this resulted in a complete cessation of serious scientific research, with very limited data published in the scientific literature and few external grants awarded. Eventually, Mr. Townsend withdrew his financial support, resulting in the eventual collapse of the organization. In December of 2013, the Ape Cognition and Conservation

Initiative was formed with a new focus on understanding the two species most closely related to humans, chimpanzees and bonobos.

The Ape Initiative was formed through collaboration between two leading researchers in ape cognition, Jared Taglialatela (Kennesaw State University) and William Hopkins (Georgia State University). Collectively, they have over 50 years of research experience with bonobos, chimpanzees, and other great apes. In addition, they have more than 30 years of continuous NIH funding for research with chimpanzees and bonobos, publishing innovative, highly impactful, ethically sound research with direct translational value that has contributed meaningfully to science. Hopkins and Taglialatela were the first laboratory in the world to do noninvasive neuroanatomical and functional brain imaging in chimpanzees and the first to demonstrate voluntary control of vocalizations in bonobos and chimpanzees.

## Ape Initiative's Resources

Bonobos are a critically endangered species of great ape found exclusively along a relatively small section of the Congo River Valley in Central Africa. The name "bonobo" was believed to come from the misspelling of a village in the Congo called Bolobo. Chimpanzees and Bonobos have been recognized as distinct species since 1933. Bonobos have black faces with pink lips from birth, long black hair that is parted in the middle of the head, and hardly any chin hair, primarily eat fruit, travel on the ground during the day and nest in the trees at night, have a strong bond between mother and child that lasts until adulthood, and have a matriarchal society where the females play an integral role in the social structure. There are fewer than 200 bonobos in captivity outside of Africa.

The Ape Cognition and Conservation Initiative is situated on 230 acres in Des Moines, Iowa, in the Des Moines River Valley. The five bonobos currently living at the Ape Initiative are Kanzi, Elikya, Nyota, Maisha, and Teco. All of the bonobos participate in cognitive and behavioral research aimed at both enriching their lives and

**Ape Cognition and Conservation Initiative (ACCI), Fig. 1** Photograph shows indoor enclosure (top left), touchscreen workstation (top right), and aerial view of outdoor yards and facility (bottom). The Ape Initiative is

situated on 230 acres in Des Moines, Iowa. The apes have access and freedom to move through 6 acres of indoor and outdoor space. Photo from Jared Taglialatela, personal collection

helping researchers at the Ape Initiative uncover the evolutionary origins of human cognition and behavior (Fig. 1).

Kanzi (born in 1980) is internationally known for his English comprehension and symbol use. He is heralded as the first nonhuman primate to make stone tools and construct a fire. Kanzi can comprehend novel spoken English sentences (Savage-Rumbaugh et al. 1993). When he is introduced to a new object that he does not have a word for in his lexigram vocabulary, he combines symbols to describe the new item (Savage-Rumbaugh and Lewin 1994).

Nyota (born in 1998) is the son of Kanzi's late half sister, Panbanisha. Nyota appears to understand some spoken English and frequently uses the lexigrams to actively participate in his daily routine. His language skills remain scientifically unknown, but the Ape Initiative is currently experimentally evaluating both his lexigram symbol use and spoken English comprehension.

Maisha (born in 2000) is the last-born son of Matata. Maisha spends his days interacting with the rest of the bonobos in the Ape Initiative's care and foraging in over 6 acres of outdoor space at the Ape Initiative. Based on his parentage, Maisha has a diverse genetic makeup that is underrepresented in captive bonobo populations. He will play an important role in The Ape Initiative's conservation efforts.

Elikeya was born to Matata in 1997 and is Maisha's full sibling. She became the de facto matriarch of the Ape Initiative's bonobo group when Matata died in 2014. Elikeya showcases the importance of mother-son relationships in bonobos by spending a significant amount of time with her only offspring, Teco. Elikeya has not been tested on language comprehension but does participate in both touchscreen-based computer tasks and cognitive testing. Like Maisha, Elikeya will play an important role in bonobo conservation efforts.

Teco (born 2010) is the youngest of the bonobos at the Ape Initiative and the only bonobo born in the state of Iowa. Teco's behavior suggests that he does have some comprehension of the lexigrams and spoken English, but his linguistic capacity is currently unknown. Like his father, Nyota, the Ape Initiative is in the process of experimentally determining his linguistic competency.

The physical laboratory space at the Ape Initiative includes several strategically located touchscreen workstations to afford facile ape keyboard communication both within and between the subjects and researchers. Touchscreen workstations can also be configured to allow the apes to manipulate elements of their environment such as doors, remote cameras, and vending devices. In addition, the workstations allow researchers to administer computer-based tests to the subjects. Strategically placed IT connections allow for IP-based cameras, microphones, and other devices to be configured and reconfigured as research needs dictate the need for the collection of behavioral and communication data from the bonobos. The apes are also afforded control over major aspects of the building environment and may freely visit over 6 acres of outdoor areas (weather-permitting) with groves of trees and climbing structures around a lake providing researchers with unprecedented data collection opportunities.

## Future of Ape Initiative

In the future, the Ape Initiative aims to expand in terms of both the number of bonobos at the facility and the range of species available for scientific inquiry. The bonobo species survival program (SSP) and the Ape Initiative are currently working together to enhance the genetic diversity of the captive bonobo population by planning to add the five bonobos living at the Ape Initiative to the SSP. In addition to improving the viability of the captive population of this critically endangered great ape, this will allow the Ape Initiative to increase the number of subjects available for research. Additionally, the Ape Initiative is considering the addition of chimpanzees to its population of great apes to conduct comparative research with the two species that are most closely

related to humans. Achieving this goal would allow unprecedented comparative research. With the addition of chimpanzees, the Ape Initiative would be the only dedicated research facility in North America to house chimpanzees and bonobos and one of only two in the world.

The long-term research goal of the Ape Initiative is twofold. The Ape Initiative is working to expand our knowledge of the two species most closely related to humans and disseminating these findings via the publication of manuscripts in peer-reviewed scientific journals. Further, the Ape Initiative is working on disseminating findings to the public and educational organizations via formal training and community outreach. By continuing to conduct behavioral and cognitive research in a noninvasive and collaborative environment, the Ape Initiative's unique research can reach a broad audience both locally and internationally. The potential for international recognition and research funding through collaborative efforts cannot be overstated.

The Ape Initiative is working with the best and brightest investigators to carry out sophisticated and impactful research on great apes. By doing this, The Ape Initiative is becoming a premiere center for the study of comparative ape cognition. The Ape Initiative is using the results of behavioral and cognitive research to help improve the management and sustainability of captive populations as well as inform conservation efforts in range countries. The Ape Initiative is continuously developing education programs that aim to inform students of all ages about the two species most closely related to humans. During its relatively short history, The Ape Initiative has developed an internationally recognized research program that aims to not only gain unprecedented insight into the origins of our own species but also to gain knowledge that will help improve the welfare, and increase our understanding of, chimpanzees and bonobos.

## Synonyms

[Warning coloration](#); [Warning displays](#); [Warning signals](#)

## Definition

A characteristic that signals to potential predators that an animal is unprofitable as prey

## Introduction

Many animals are toxic, unpalatable, or otherwise unsuitable as prey items to potential predators. Such species often advertise their unprofitability to predators using warning signals, which is referred to as aposematism. This is generally advantageous to both predator and prey: the former avoids the costs of pursuing an unsuitable meal (ranging from wasted energy to illness or death) and the latter avoids a predation attempt. Aposematic signals contain two components: a secondary defense used upon attack by predators – such as chemical toxicity – that makes the prey unprofitable and a primary defense – such as a distinctive color or odor – that advertises this unprofitability and therefore functions to prevent attack. For instance, ladybird beetles are toxic to predators and advertise this with brightly colored (red, orange, or yellow) wings with black spots (Arenas et al. 2015). Aposematism is a well-studied topic within evolutionary biology, and aposematic signals have been found in many species across the animal kingdom. Extensive research has also been conducted documenting both learned and naïve predator responses to aposematic prey.

The concept of warning signals was originally proposed by Alfred Russel Wallace (1889) as an explanation for the bright colors often displayed by caterpillars, which at the time were seemingly at odds with the theory of natural selection. Wallace referred to the advertisement of noxious qualities as “warning coloration,” and the vast majority of early studies focused on colorful aposematic signals in the visual modality; however, warning signals have now been demonstrated in many sensory modalities and aposematic signals can include visual, acoustic, olfactory, gustatory, and behavioral components. The term “aposematism,” derived from the Greek *apo* (away) and *sema* (sign), was coined by Edward Poulton (1890) to describe Wallace’s concept of

warning coloration in his proposed nomenclature of antipredator defenses.

## Evolving Aposematism

Aposematism has been characterized as a paradoxical adaptation. Whereas there are clear benefits to advertising unpalatability to predators and aposematic signals have been documented in many species, the processes by which aposematic traits have originated are less straightforward. The effectiveness of aposematic signals increases with their density, yet aposematic species are also generally more conspicuous than their cryptic counterparts. How would the first individuals with mutations that increase conspicuousness survive long enough to facilitate predator learning and therefore gain a selective advantage?

Multiple hypotheses have been proposed to address this “rare conspicuous mutant” problem (reviewed by Mappes et al. 2005; Ruxton et al. 2004; Skelhorn et al. 2016). Some focus on stochastic events such as the temporary absence of predators, chance survival of mutants, or random shifts in prey population dynamics. If aposematism evolves by chance in one region, it can then spill over into neighboring populations. Species traits may also be important. A tendency for similar individuals to aggregate (potentially but not necessarily because they are closely related) could give rise to aposematism because the concentration of similar prey items aids in predator learning and dilutes the costs per individual, thus allowing even a small number of early aposematic individuals to give rise to predator avoidance. Similarly, better secondary defenses in conspicuous individuals can lead to increased survival rates from predation attempts and quicker predator learning. Characteristics of predator psychology and perceptual mechanisms may also be important. Predator characteristics such as neophobia (avoidance of novel items) and dietary conservatism (a preference for familiar food items) may explain the perpetuation of early mutants. Conspicuous aposematic signals may also interact with predator perceptual systems in

ways that facilitate rapid learning and retention. Predatory-prey dynamics may also play a role. For instance, the presence of more profitable prey species may ease selection for crypsis, and there is increasing evidence that strategic decision making by predators may be important. Multiple explanations can also be combined into more complex models of the evolution of aposematism, and modeling and simulation studies have demonstrated varying circumstances in which aposematism can arise and be maintained.

Another option is to circumvent the rare conspicuous mutant problem, postulating that aposematism can originate without an initial mutation event (reviewed by Ruxton et al. 2004). Aposematic signals could arise because they confer advantages in other contexts such as mating (i.e., via sexual selection), foraging, or thermoregulation, with evolution proceeding based on multiple selective pressures. Similarly, when prey are densely populated and the likelihood of detection by predators is high, relaxed selection on crypsis may allow for the evolution of aposematic signals. Aposematism could also develop following a rapid environmental change that causes a previously cryptic signal to become conspicuous. Finally, when defenses are visually apparent, such as sharp spines, increased conspicuousness may simply amplify the salience of an existing visual cue. It is important to note that these hypotheses are not mutually exclusive, and that aposematism, which has evolved multiple times across animal groups, may have done so via different routes in different species.

Phylogenetic analyses and reconstructions can be informative when studying trait evolution and can help to understand the context in which aposematism has arisen (reviewed by Härlin and Härlin 2003; Ruxton et al. 2004). For instance, in some animal groups aposematism is associated with prey aggregation, but aposematism appears to be the older trait, suggesting that prey aggregations were unlikely to have influenced its evolution. More research involving phylogenetic comparative analyses is likely to uncover other interesting trends.

## Signal Form

Why do aposematic signals look the way they do? A good warning signal should facilitate predator learning and long-term avoidance. Although aposematic signals are diverse, they also share many common characteristics that are related to their function.

Aposematic signals are generally conspicuous and include components such as bright colors or strong odors. There are a variety of (non-mutually-exclusive) reasons why conspicuous colors may be particularly suited to a warning signal (reviewed by Ruxton et al. 2004; Stevens and Ruxton 2012). Conspicuousness can facilitate detection by predators at a distance and may prevent cases of mistaken species identity. Conspicuous signals may also facilitate predator avoidance due to biases in predators' psychology. Conspicuous signals may enhance predator wariness, accelerate predator learning, decelerate forgetting, and increase prey recognition accuracy relative to other types of signals. They might also help to maintain an honest system (see next section) because the costs of conspicuousness without a backup secondary defense are too high for other species to pay. Whereas conspicuousness is often considered a defining trait of aposematism, the benefits of conspicuousness may saturate, however, leaving some aposematic species only moderately conspicuous. This may be caused by factors such as physiological costs to signal production, variability in predator behavior, trade-offs between various selective pressures, or viewing distance effects.

In addition to general conspicuousness, aposematic signals often include other similar elements (reviewed by Ruxton et al. 2004; Stevens and Ruxton 2012). Simple patterns with repeated elements are common. Simple patterns and redundant components may facilitate predator learning, and repeated elements may also increase contrast if they are rare in the environment. Aposematic signals also often involve similar colors, generally reds, yellows, and black. This could be because by using similar colors, aposematic species can reduce species-level learning costs when

predators learn (either individually or across evolutionary time) to generally avoid these commonly aposematic colors. In Müllerian mimicry (this volume), multiple aposematic species converge on a very similar phenotype, which is beneficial to all species involved. However, the common use of reds, yellows, and black may also be related to characteristics of the environment. Compared to other colors, reds and yellows contrast strongly against a green foliage background, remain distinctive in different lighting conditions, are distinctive in terms of both color and brightness, are distinctive from many other species, and may blend at a distance to create distance-dependent camouflage (i.e., the prey is camouflaged to avoid detection at a distance, but once a predator gets close they are conspicuous and advertise unprofitability) (Stevens and Ruxton 2012). This highlights the importance of considering ecology and species characteristics (e.g., different predators see colors differently) when studying aposematic signals.

Despite these general characteristics, aposematic signals remain variable both within species and between closely related species (Stevens and Ruxton 2012). This is somewhat puzzling because selection would be expected to favor close similarity between signals to facilitate predator learning. This diversity could be maintained by variation in the environment or predator community (e.g., across seasons or space), which could cause different morphs to be more successful in different times or areas. Additional selective pressures may also be involved, with phenotypes representing a trade-off between aposematism and other factors such as sexual selection.

## Signal Honesty

Do aposematic signals consistently reflect underlying qualities linked to prey unprofitability? Work on honest signaling has often focused on the handicap hypothesis (this issue), which posits that high costs associated with producing signals can prevent cheaters because low quality individuals cannot afford to pay. But aposematic signals

are not necessarily handicaps and the mechanisms of signal production and secondary defenses are not always linked (Guilford and Dawkins 1993; Ruxton et al. 2004). Conspicuous aposematic signals are often honest indicators of prey unprofitability in a qualitative sense because prey without secondary defenses such as toxicity are not able to pay the survival costs of being more noticeable to predators (reviewed by Summers et al. 2015). Without the secondary defense to back them up, the conspicuous signals associated with aposematism would lead to increased predation rates and lower fitness. The major exception is Batesian mimicry (this volume), in which an unprotected species mimics an aposematic species to gain the fitness advantages enjoyed by the latter without incurring the costs of defense. Batesian mimicry is well documented, but the local population density of mimics tends to be lower than that of the aposematic species they mimic because as the ratio of honest signalers to cheaters increases the degree of protection offered by the signal decreases.

Some aposematic species also exhibit quantitatively honest signals, where there is a positive correlation between the strength of aposematic signal and degree of unprofitability to predators (reviewed by Summers et al. 2015). This appears to be less common than qualitative honesty, although more research is needed. Quantitatively honest aposematic signals may be particularly likely when the signal is morphologically or physiologically linked to the method of defense.

## Conclusion

Aposematism has been a major research focus of biologists since the early days of evolutionary thinking. While the benefits of advertising unprofitability to predators seem straightforward at face value, some aspects of aposematism are perplexing, including aspects of its origin, the presence of intragroup variability, and less conspicuous aposematic signals. Aposematism remains a common interest in biology, and continued work in this area will likely contribute to our knowledge of the process of evolution and the

mechanisms that generate the incredible diversity of life on earth.

### Synonyms

Appearance versus reality; False perception; Visual illusions

### Definition

The ability to distinguish how an object perceptually appears from how it truly is.

### Introduction

Perception is not always veridical. Properties of objects, such as their shape, size, or color, can be perceived falsely due to factors such as illumination, refraction, and misleading contextual cues. Such perceptual mistakes are demonstrated by a wide variety of optical illusions (Palmer 1999). Misperception can also involve mistaking objects for other objects due to similarities in their surface features; for example, a fur coat thrown onto the floor may be mistaken for a dog. In some cases, the deceived individual is aware of falsely

perceiving the object, while maintaining knowledge of its true nature and further recognizing that the two are at odds. This demonstrates a capacity for appearance reality (AR) discrimination.

There are many examples in nature of appearance–reality disjunctions, including cases of camouflage in predators and prey, false eye spots on moth or butterfly wings, and simple cases of mistaken identity, such as misperceiving a stick as a snake. From an evolutionary point of view, the ability to distinguish the appearance of objects from their true nature provides clear adaptive advantages. Knowing true danger from apparent danger allows animals to protect themselves and their offspring while avoiding unnecessary expenditures of energy. When foraging for food, it is advantageous to distinguish edible from non-edible items, objectively larger from smaller food sources, and higher calorie items from lower calorie ones, regardless of any misleading appearances that occur. Even greater advantages can be gained by recognizing when other individuals are experiencing a false perception, and then using this knowledge to one's own advantage. A subordinate animal that recognizes when a competitor falsely perceives a nut as a stone, for instance, could wait until the competitor leaves the area before attempting to eat the nut. Indeed, the challenges of foraging, especially in competition with other individuals, are thought to have been one of the evolutionary forces driving expansions in brain size and increased intelligence in primates (Dunbar and Shultz 2007).

In addition to its evolutionary significance, AR discrimination may play an important role in social–cognitive development. Developmental researchers have found that children who pass tests requiring insight into their own mistaken perceptions of deceptive objects also expect others to be fooled by those same objects (Gopnik and Astington 1988; Moll and Meltzoff 2011). It has thus been suggested that AR discrimination could support the development of misrepresentation more generally. Becoming aware that objects can be falsely perceived by oneself, for example, could be a stepping stone to inferring false perceptions in others, which could in turn provide a basis for understanding false belief

states (Krachun et al. 2016; Lurz 2011). Given the evolutionary and developmental importance of AR discrimination, researchers have created a variety of tests to study this cognitive ability. The earliest tests were designed for preschool children, with later tests being developed to test AR discrimination in great apes. As the tests for apes were borrowed from the procedures designed for children, the children's tests are described first below, followed by the more recent tests for apes.

## AR Tests with Children

Empirical research on AR discrimination began with developmental research on human children. The primary goals of this research were to identify at which age this cognitive ability emerges, and to investigate its relationship to other cognitive abilities such as visual perspective taking and false belief understanding. The classic tests for children involve presenting them with an object whose appearance is at odds with its true identity, function, or properties. In the rock-sponge test (Flavell et al. 1986), for example, children are shown a sponge that looks convincingly like a rock, and they are then given the opportunity to handle the object and discover its true identity. To pass the test, children must correctly answer questions about what the object looks like and what it really is. The rock-sponge test makes use of what is called an "identity illusion" because the appearance of the object is misleading with regard to its true identity. Other AR tests for children use what are called "property illusions" because they create a contrast between the real and apparent perceptual properties of items. In one such test, for example, the experimenter places an object behind a transparent, colored filter and then questions children about the object's real and apparent color (Flavell et al. 1986). In other tests, children are asked to comment on the real and apparent size or shape of objects whose appearance is altered by various means; for example, a straight stick looks bent when placed in a glass of water, or an object looks bigger or smaller when placed behind a magnifying or minimizing lens (Braine and Shanks 1965; Taylor and Flavell 1984). Numerous studies

show that children begin to pass such tests reliably by 4–5 years of age. Younger children may also succeed when language demands are reduced, such as when children make nonverbal behavioral responses rather than verbally answering direct questions about the objects (Moll and Tomasello 2012; Sapp et al. 2000).

An important finding, with regard to the role of AR discrimination in cognitive development, is the similarity in children's performance on AR tests and their ability to attribute false perceptions and false beliefs to others. A comparable dramatic improvement in children's performance in all three types of test occurs in the 4–5 year age range. Additionally, for both verbal AR tests and false belief tests, there is evidence that younger children's difficulties may be due to misinterpreting the test questions (Deák 2006). Significant positive correlations in performance on AR tests and both false perception tests (Krachun and Lurz 2016) and false belief tests (Gopnik and Astington 1988) have also been observed. These parallels are thought to reflect the fact that all three tests rely upon a capacity for dual representation, the capacity to entertain two different representations of the same object (Flavell 1993; Perner et al. 1987).

## AR Tests with Great Apes

Given the boost to survival and reproductive success conferred by AR discrimination, it is reasonable to think the ability could be an evolved capacity across a range of species, not just humans. However, the extent to which non-human animals are capable of recognizing their own false perceptions and making AR discriminations is still largely unknown. The only direct investigations of AR discrimination in non-humans to date include a handful of studies with great apes, including chimpanzees (Karg et al. 2014; Krachun et al. 2009, 2016), as well as bonobos, gorillas, and orangutans (Karg et al. 2014). Unlike tests with humans, the goal has not been to determine when AR discrimination emerges during development but, rather, to determine whether apes possess this cognitive ability

at any age, even in adulthood. To this end, some juveniles but mostly adult apes have been tested, with the age of subjects ranging from 6–42 years old. The tests developed thus far use an object-choice format in which apes are allowed to choose between two items by pointing to the one they wish to receive from an experimenter. In these tests, researchers have taken advantage of apes' demonstrated strong preference for greater amounts of food over lesser amounts. When given a choice between a larger piece of food and a smaller piece of food, for example, almost all apes consistently choose the larger piece (e.g., see Krachun et al. 2009).

Capitalizing on these preferences, AR tests offer apes a choice between one item that perceptually *appears* to be the more desirable one but is actually the less desirable one, and vice versa. In order to obtain the truly more desirable item, the ape must point to the one that appears to be the less desirable item. A variety of illusion-producing stimuli have been used to create disjunctions between the appearance and the true nature of the choice items, including magnifying and minimizing lenses (Krachun et al. 2009, 2016), mirrors and color filters (Krachun et al. 2016), and boards that are used to partially occlude food items such that the truly longer item looks shorter and vice versa (Karg et al. 2014). The general procedure runs as follows: apes are first given the opportunity to view the food items in their natural state, and they then observe as an experimenter places the same items into their illusory context (e.g., behind the distorting lenses or occluding boards). Thus, the apes know about the true properties of the items, and they can see how placing the items into their illusory context causes their appearance to change. With the items displayed in their illusory context, the ape is then allowed to choose between the items. Apes that are not misled by the deceptive appearance of the items are expected to choose the apparently less desirable item in order to obtain the truly more desirable one. Repeated trials and sessions are administered (typically 12 trials per session over 2–8 sessions) with the location of the truly more desirable food item randomized across trials.

Results from tests using this procedure provide support for the idea that apes are capable of discriminating appearance from reality. Karg et al. (2014) found that across all four species of great ape, the truly more desirable food item was chosen in approximately 85% of trials. Krachun et al. (2009) did not find statistically significant results at the group level for the chimpanzees who participated in their AR test with distorting lenses; nevertheless, at the individual level, 57% of the chimpanzees chose the truly more desirable food item significantly more often than chance across all the trials administered. In Krachun et al. (2016), the percentage of chimpanzees doing so ranged from 50% to 100%, depending on the test. These combined results suggest that some, if not all, apes are capable of ignoring the misleading appearance of the items at the time of choice and choosing the apparently less desirable, but truly more desirable, item.

As with all tests investigating the cognitive abilities of nonhuman animals, efforts must be made to rule out explanations that appeal to lower-level cognitive processes than those being tested. In the case of the AR tests described above, Krachun et al. (2009) raised the possibility that apes could succeed by noting the initial location of the truly more desirable item and then simply choosing that location at the time of choice, without necessarily attending to the misleading appearance of the items in their illusory context. This strategy is made possible by the fact that the location of the truly more desirable item remains constant throughout the duration of each trial. In light of this, some AR studies (Krachun et al. 2009, 2016) have included a more challenging test that makes it impossible for apes to succeed using this simple method. This test differs from the simpler one in that once the experimenter has placed the items into their illusory context in full view of the ape, he/she then blocks the ape's view with a visual occluder, arranges the items on the table, then removes the visual occluder and allows the ape to choose between the two items. Thus, in this version of the AR test, although the ape sees the change in appearance of the items as they are placed into their illusory context, the final location of the truly more desirable item (e.g., the truly

larger one) is determined out of view of the ape. The only way that the ape can know the location of the truly more desirable item is to visually examine the items before making a choice, and to find and choose the item that *appears* to be the less desirable one. As this procedure makes it impossible for apes to simply track the location of the desired item throughout the trial, it is referred to as a “tracking” control test. Some apes that succeed with the simpler procedure are unable to pass this more challenging test, but other individuals continue to choose the truly more desirable food item significantly more often than chance under these conditions (Krachun et al. 2009, 2016). The reasons for these differences across individuals is unknown, but possibilities include differences in working memory, attention, motivation, and the ability to inhibit impulsive responding. Another possibility is that AR discrimination abilities may not be universally acquired in our closest ape relatives in the same way that they are by typically developing humans.

### The Reverse Contingency Argument

When interpreting the results of AR tests with apes, another possibility that must be considered is that successful apes could be using a “reverse contingency” rule to solve the problem. In an object-choice task, a reverse contingency rule means that obtaining the preferred reward is contingent upon choosing the nonpreferred reward. In a choice between a small and a large food reward, for example, the animal must point to the small reward in order to obtain the large reward from the experimenter. Similarly, if given a choice between two groups of food items, the animal must point to the group with fewer items in order to obtain the group with more items. In a series of studies using such reversed reward contingencies for both different-sized items and different numbers of items, Sally Boysen and her colleagues demonstrated that chimpanzees have an extremely difficult time with these tasks, often requiring hundreds of trials before they are able to master them (Boysen and Berntson 1995; Boysen et al. 2001). Their poor performance has been attributed to inadequate inhibition of an innate, evolved

impulse to reach for the greater amount of food, known as a prepotent response tendency. Apes’ consistently poor performance in reverse contingency tasks demonstrates that those that pass AR tests are unlikely to be doing so by learning a reverse contingency rule. This is because they are able to master AR tests in far fewer sessions than it typically takes them to master reverse contingency tasks. For example, Krachun et al. (2009) directly compared chimpanzees’ performance on an AR test with their performance on a matched reverse contingency task. The chimpanzees performed significantly better in the former than the latter, confirming that apes were not passing the AR test by using a reverse contingency rule.

### Related Cognitive Abilities and Tests

Although just a few studies have directly investigated AR discrimination in apes, a variety of other tests may tap into cognitive abilities that rely upon AR discrimination, or that share elements with AR tests. For example, “conservation” is the ability to recognize that the amount of a substance remains constant across changes in shape or arrangement that affect its appearance (Piaget and Inhelder 1974). In the classic liquid-conservation task for children, participants watch as the liquid from one of two identical containers is poured into another container with different proportions (e.g., taller and narrower than the original). Children are then asked whether the amount of liquid in the new container is the same as, or different from, the amount of liquid in the original container. Some investigators (e.g., Braine and Shanks 1965) have theorized that succeeding in conservation tests requires an understanding of the distinction between appearance and reality. Nonverbal conservation tests have been devised for apes, and these animals have had some success in these tests (Suda and Call 2004; Woodruff et al. 1978). However, it is unclear to what extent the apes relied upon strategies that involved discriminating appearance from reality. For example, they could have succeeded by tracking the larger amount of liquid through the transfer from one container to the

other, or by estimating the two quantities by visual inspection after the transfer was complete.

Another cognitive ability that shares features with AR discrimination (as well as with conservation) is “essentialism.” This is the understanding that the true identity or essence of an object remains unchanged despite changes in its superficial features. A common example used to illustrate essentialism is iron pyrite (fool’s gold): despite its superficial similarities to gold, iron pyrite is not the same kind of substance as gold. Cacchione et al. (2016) created a test for essentialism in chimpanzees that uses a standard object-choice paradigm. As in AR tests designed for apes, the choice in the essentialism test is between a preferred item and a nonpreferred item (e.g., slice of banana versus slice of carrot). Apes observe as an experimenter makes the items perceptually identical to one other, for example, by wrapping a banana peel around the outside of the carrot slice and painting the top of it yellow. Thus, the apes are faced with a choice between two items that look the same but are essentially different. Cacchione et al. (2016) found that when given a choice of this kind, the apes preferred the banana to the carrot, despite their identical appearance (provided the working memory demands of the task were sufficiently low and the ape’s motivation was sufficiently high). Thus, the apes chose according to the true identity of the objects, not according to their appearances. On this basis, the researchers suggest that apes may possess a basic form of essentialism that relies upon recognizing when the appearance of an object is incongruent with its true identity, which sounds very much like what children do in the identity-illusion AR tests described earlier. It should be noted, however, that these findings are subject to the same lower-level explanation given for apes’ success in the AR tests described above. A tracking control, similar to that devised for the AR tests, could rule out this alternative explanation.

## Extensions of AR Tests in Animals

Beyond testing for apes’ ability to tell real from apparent, AR tests for apes may also provide a novel way of testing other cognitive abilities, such

as metacognition. Metacognition is the ability to know about one’s own mental states and processes, such as knowing that you can remember someone’s name, or knowing how confident you are about a judgement you have made. In research with human children, AR discrimination is generally considered to be a form of metacognition (Flavell et al. 1986). This is because in order to answer correctly the questions posed to them in the standard verbal tests (e.g., “Does this look like a rock/sponge? Is it really a rock/sponge?”), children must be aware of their own perceptual states (i.e., how things perceptually appear to them), and such awareness is a form of metacognition. For over 20 years, researchers have been using a variety of experimental methods to investigate metacognition in nonhuman animals (Smith et al. 2012). As successful AR discrimination in children is considered a form of metacognition, it has been suggested that nonverbal AR discrimination tests could also be used to study metacognition in nonhuman animals (Call 2012). However, Call (2012) is cautious about this new approach, in part because nonverbal AR tests do not require subjects to report on how objects look to them, as verbal AR tests do. This raises the possibility that subjects could pass the nonverbal AR tests without being aware of their own perceptual states. Nevertheless, proper control procedures, such as tracking controls (above), may be able to rule out such nonmetacognitive explanations of successful performance on nonverbal AR tasks (Krachun et al. 2016).

Recently, developmental researchers have begun to apply methods from AR discrimination tests to test children’s ability to make inferences about others’ mental states, called “theory of mind.” Specifically, such tests have made use of illusory stimuli to investigate children’s understanding of others’ visual perspective (Moll and Meltzoff 2011), false perceptions (Krachun and Lurz 2016), and false beliefs (Buttelmann et al. 2015). To succeed in the tests, children must use their own experience with a visual illusion to infer that another individual will experience the illusion in the same way. It has been suggested (Krachun and Lurz 2016; Lurz 2009) that the “experience-projection” aspect of these tests makes them particularly useful for investigating theory of mind in

animals, because it removes the opportunity for animals to use behavioral or environmental cues to succeed. Given that the possible use of such cues (rather than inferences to mental states) by animals in theory of mind tests has been a controversial issue for decades (Povinelli and Vonk 2003), this is an important new direction in animal theory of mind research. In line with this new direction, Karg et al. (2016) used illusory stimuli in a task designed to test chimpanzees' understanding of mistaken perception in a naïve competitor. Although results did not show that chimpanzees understood the mistaken perceptions of the competitor, the study heralded in a new, innovative method for investigating theory of mind in animals.

## Defining and Characterizing Appetitive Responding

Early components of a behavioral sequence may be referred to as appetitive, and late components may be referred to as consummatory. Appetitive responses have been characterized as variable, plastic, and purposive, whereas consummatory responses have been characterized as rigid, simple, and “automatically discharged” (Eibl-Eibesfeldt 1970; Tinbergen 1951).

Understanding the concept of appetitive responding requires attention to both appetitive and consummatory responding and their origination. Early concepts of appetitive and consummatory behaviors were first elaborated on by Craig (1918). Craig (1918) originally characterized appetitive responses as restless, varied forms of activity that served to orient an animal toward an object. Consummatory responses were innate responses consisting of what he referred to as “species-specific constancy.” Traditional ethological views (e.g., Tinbergen 1951) described species-typical behavior as consisting of sequences of appetitive responses and consummatory responses. Responses at the beginning of behavior sequences were referred to as appetitive, whereas the terminal responses at the end of behavior sequences were referred to as consummatory. Appetitive responses have been viewed as variable, plastic, and purposive, whereas consummatory responses have been characterized as rigid, simple, and “automatically discharged.” This perspective implies that appetitive components of behavior may be more susceptible to modification by conditioning than consummatory responses. However, there are numerous published examples suggesting a great deal of plasticity to what were once thought of as rigid and fixed consummatory behaviors.

Pavlov's classic method of studying what is learned about a conditioned stimulus (CS) that predicts an unconditioned stimulus (US) also illustrates a dichotomy of appetitive and consummatory responding. For example, a rodent is presented with a lever (CS) paired with a food pellet (US). After repeated pairings of the CS and US, the lever becomes a conditioned stimulus and may evoke motivation on its own. During

conditioning, the CS may elicit appetitive responses such as orientation to the CS as well as consummatory responses similar to those predictive of the US (i.e., licking, biting, and sniffing of the CS). An animal that directs responses toward the CS during conditioning is considered to be “sign tracking” as opposed to making responses toward the US (“goal tracking”). Goal trackers use the CS to signal impending food. Therefore, during presentation of the CS, they move toward the US. Sign tracking behavior involves an animal perseverating toward the CS rather than toward the US, which reduces the likelihood they will gain access to reward. Numerous drug studies have demonstrated that animals that have a high propensity to sign track attribute greater motivational value to the cues (CSs) associated with a drug (US) and are therefore more sensitive to the drug cues (see Robinson et al. 2014 for review). This sensitivity to drug cues may later result in drug-seeking behavior that might ultimately lead to relapse. Thus, appetitive sign tracking behavior has implications for vulnerability to drug abuse.

Appetitive responding also has roots in operant conditioning procedures. In Skinner’s classic experiment Skinner (1948) involving superstitious behavior in pigeons, food was presented at regular intervals and no behavior was required. Skinner reported that pigeons developed behaviors such as turning counterclockwise about the cage or thrusting its head into one of the upper corners of the cage just prior to food delivery. The pigeons were exhibiting the same behaviors that they were engaging in when the food first became available. Timberlake and Lucas (1985) referred to these behaviors as classically conditioned appetitive responding.

Investigators of animal behavior in laboratory paradigms have also distinguished between “early” and “late” response components when studying more complex behaviors. For example, Konorski (1967) viewed feeding behavior in terms of preparatory and consummatory responses. Preparatory responses involved the elicitation of hunger and searching behavior, whereas consummatory responses involved reflexes beginning with the arrival of food in the mouth. According to Konorski’s model, when a

cue was paired with the opportunity to eat, the conditioned response (CR) that resulted depended on the nature of the cue and when it was introduced during conditioning (i.e., as conditioning became better established, consummatory CRs replaced appetitive hunger CRs). This idea has been elaborated on more recently by Timberlake and his associates as the behavior systems theory (Timberlake and Lucas 1989). Behavior systems theory invokes a hierarchy of control mechanisms consisting of a series of modules organized in a temporal-spatial sequence, with general search and focal search behaviors at one end of the continuum and consummatory behaviors at the other end. Behavior systems theory was developed in an attempt to combine concerns about control of functional behavior with concerns of the role of learning in eliciting new responses and stimulus control.

## The Nature of Appetitive Responses

### Food

Early experiments using animal models typically studied consumption to assess many aspects of food reward but did not account for appetitive behavior. Hodos (1961) was the first to establish a reliable animal model to measure the strength or motivational value of a food stimulus using an appetitive behavior paradigm. Rats reliably pressed a lever for a sweet milk reinforcement, and the amount of effort they were willing to expend was a metric of reward strength. The degree of effort expended to obtain sucrose was tightly correlated with preference for and consumption of the same concentration. More recent animal models have studied appetitive behavior to examine the reward strength or motivational value of food.

### Sex

Frank Beach was among the first researchers to make a distinction between arousal and performance components (appetitive and consummatory, respectively) in male rats. Subsequent lesion studies further dichotomized appetitive and consummatory sexual behavior demonstrating that lesions to the medial preoptic area

(mPOA) eliminated copulatory behavior but not appetitive behaviors (e.g., Meisel and Sachs 1994). Thus, studies of male sexual behavior distinguish sexual motivation (i.e., “libido”) from the performance of copulatory acts. Similarly, studies in male Japanese quail that have utilized both pharmacological manipulations and lesions provide further functional evidence for the appetitive-consummatory distinction.

## Drugs of Abuse

Numerous drugs of abuse, in particular, psychostimulants, elicit appetitive responses that occur in the absence of drug administration. In animals, these appetitive responses typically take the form of compulsive drug-seeking behavior, and they may mimic various aspects of drug relapse in humans (e.g., Weiss et al. 2001). For example, environmental cues that become associated with the subjective effects of a drug may later evoke drug craving. Animal models demonstrate craving via drug-seeking behaviors by showing a preference for a place where they experienced the drug (i.e., a conditioned place preference) or by working for a drug (i.e., lever pressing).

## Neural Substrates of Appetitive Behaviors

Appetitive behaviors are primarily driven by the nature of the reward (e.g., sex, drug, food). Numerous structures are involved in reward-related processing including the hippocampus, prefrontal cortex, and ventral pallidum. However, the majority of research on appetitive behaviors implicates the involvement of the ventral tegmental area (VTA) and nucleus accumbens (NAc). These areas comprise the mesolimbic and mesocortical pathways that make up the reward circuits in the brain via dopaminergic neurons.

The VTA primarily consists of dopamine (DA) neurons and is implicated in many conditioned appetitive responses, specifically those responses associated with processing reward stimuli that motivate an appetitive response (Fields et al. 2007). Additionally, the NAc has both

afferent and efferent DA projections to and from the VTA, and it has long been viewed as the prominent “reward” center of the brain. For this reason, there is a plethora of information about the role of the NAc in appetitive behavior. The NAc has been shown to be involved with approach behaviors for reward-predicting stimuli, and blocking dopamine (DA) transmission in the NAc decreases approach to predictive stimuli in rodents.

## Conclusion

Historically, appetitive responses have been identified and studied as separate from consummatory responses, and observations of animal behavior reinforce the validity of this distinction. There are a variety of appetitive responses that have been investigated in numerous paradigms, including food, sex, and drug studies. Studies of appetitive responding typically have a motivational component such that an animal may seek out a particular stimulus. Appetitive responding is also often tested in learning experiments, and recent studies on substance abuse are focused on appetitive responding and how to extinguish those responses. Several brain structures and neural pathways have been associated with appetitive responding. However, future studies are needed to identify pathways and neural circuitry that are specific to particular types of appetitive responding.

## Approach/Withdrawal Theory

Gary Greenberg

Wichita State University, Wichita, KS, USA

T(h)eodore. C. Schneirla (July 23, 1902–August 20, 1968) was among the preeminent comparative psychologists of the twentieth century. An ardent antireductionist, he framed the study of animal behavior and comparative psychology as a holistic, integrative research program (Tobach and Aronson 1970) using both analysis and synthesis (Maier and Schneirla 1935, enlarged in 1964). This program influenced some of the most important comparative psychologists of the twentieth century (e.g., see Aronson et al. 1970). Although those influenced by Schneirla is today a relatively small group (one of the last remaining scientists trained by Schneirla, Ethel Tobach, passed away in 2015 (Greenberg 2015; see also Greenberg, Ethel Tobach, this volume)). Schneirla's ideas continue to influence the thinking of a great many contemporary scientists. Many adhere to his proposal that both psychology and biology are in essence developmental sciences. I also adhere to Schneirla's approach to the study of behavior, an orientation embracing both processes of evolution and development from an epigenetic framework (Lerner and Overton 2013; Michel and Moore 1995; Overton and Lerner 2014).

The focus of this essay is Schneirla's concept of approach/withdrawal which he first introduced in 1939 at a meeting of the American

Psychological Association: “This conception envisages negative-positive responses as fundamentally attributable to differential arousal of excitation-reaction systems which function as though they possessed distinctly different activation thresholds. Through natural selection, we may hypothecate the evolution of such mechanisms along adaptive lines. This view has utility as a hypothetical basis for understanding approach-withdrawal behavior in man” (p. 295). In developing this concept Schneirla (1959, 1965) acknowledged being influenced by others including Wundt, Darwin, Jennings, Pillsbury, and his own teacher, J. F. Shepard (Greenberg 1995). Whereas Schneirla identified this concept as a “theory,” it is at best a “pragmatic hypothesis” (Bunge 1980, p. 22) although its apparent universal application points to its lawlike character (Greenberg et al. 1991). It is useful to point out that in our still youthful history, psychology can point to no real laws (with the possible exception of the law of effect), and although we use the term theory often, we definitely have none that operate as do those in the older sciences. I direct readers to Uttal’s (2005) discussion of what theory is in science and why psychology has none.

Schneirla proposed the A/W concept as a way of understanding the origins of complex behavior in terms of simpler biphasic processes directly related to the quantitative characteristics of stimuli. “At first, he conceptualized the biphasic processes of approach and withdrawal as related to the state of the organism and the intensity of the effective stimuli, and as critical in the initiation and maintenance of activity. This concept of the biphasic approach-withdrawal concept was expanded later by considering it to be a fundamental feature both in the behavior of simple animals such as protozoa and in early stages of behavioral development of the more complex animal forms” (Tobach and Aronson 1970, p. xvi). Some examples discussed by Schneirla include the consistent lunging forward of many fishes, amphibians, and reptiles to “moving stimuli of small area [and the] snapping responses of toads depend upon quantitative properties of the stimulus” (1959, pp. 311–312); and, “An elementary type of orientation is that in which an animal

approaches a low-energy stimulus source, as a neonate kitten nears the abdomen of its mother through crudely directionalized responses to thermal and tactual stimuli from her” (1959, p. 313).

The fundamental premise behind the approach/withdrawal concept is that these response patterns underlie all complex adaptive responses and is a synthesis of several organizing concepts and principles. In their summary of the A/W theory, Raines and Greenberg (1998) described its essential elements: biphasic processes, stimulus intensity, levels of organization, plasticity and epigenesis, and maturation and experience.

*Biphasic processes* (i.e., approach and withdrawal): are characteristic of *all* animals at *all* phyletic levels and are traced to the evolution of adaptive sensory-motor systems – quite simple in lower animals, such as the light-sensitive single cells in earthworms, and complex in vertebrates mediated by the two branches of the autonomic nervous system.

*Stimulus intensity*: low-intensity stimuli elicit approach responses and high-intensity stimuli elicit withdrawal responses. This difference is true throughout the life histories of simple organisms and in the earliest developmental stages of more complex animals. Stimulus intensity refers not only to properties of the external stimulus but also accompanying internal organismic variables, which affect the perception of stimulus intensity resulting in the dimension of “effective stimulus intensity” (e.g., Helson’s 1964 adaptation level theory).

*Levels of organization* (see Greenberg, Behavioral Levels, this volume): Schneirla’s emphasis on this central organizing principle in science leads to a “psychological way” of understanding behavior in much the same way biologists (e.g., Woodger 1929) invoked the concept to develop a uniquely biological way of thinking. In this way, psychological events are not reducible to biology and physiology. Coupling this idea within the A/W concept provides a basis for identifying the lowest level of organization for adaptive functioning. McGuire and Turkewitz (1979) provided an account of the relationship of Schneirla’s concepts of *effective stimulus intensity* and *levels*.

*Plasticity and epigenesis:* species are increasingly behaviorally plastic at higher phyletic levels, as permitted by increasingly complex nervous systems. Schneirla's rejection of reductionism and biological determinism enables this increasing behavioral plasticity. Kuo (1967) referred to this as his principle of behavioral potentials, according to which organisms at each behavioral level have the potential to develop species-typical behaviors, although the realization of this potential is the result of the organism's experiential history and not from their biological endowments (i.e., genes). This rejection of biological reductionism in favor of developmental processes emphasizes that genetic expression is not determined or guaranteed but is probabilistic (e.g., Gottlieb 1970).

*Maturation and experience:* during maturation (i.e., growth and differentiation) the organism is exposed to experiences (all stimulative effects), and it is the *fused* system of maturation and experience (not their interaction) that directs the organism's behavioral development (Schneirla 1959, 1965). It is, of course, now clear that prenatal endogenous and exogenous stimulation affects behavioral development (Kuo 1967). Gottlieb (2001, p. 2) referred to these types of stimulation as nonobvious experiences. "As for nonobvious experiences, who would have dreamed that squirrel monkeys' innate fear of snakes derives from their earlier experience with live insects...? Or that chicks perceiving meal worms as edible morsels is dependent on their having seen their own toes move...?"

Which of these biphasic processes is activated in an organism depends on the stimulus and its intensity. Of course, even identifying just what a stimulus is can be difficult "We often naively assume that 'the stimulus' we present to an organism is 'the same stimulus' it responds to" (Greenberg et al. 1991, p. 41). As an example, Tronick (1967) showed that a radially decreasing shadow is an effective imprinting stimulus, a result predicted by A/W theory. However, Tronick pointed out that such a stimulus was one that increased in intensity – a decrease in the area of a shadow resulting in a brighter visual intensity. Clearly, the crucial dimension of stimulus

intensity depends a great deal on understanding the state of the perceiving organism. McGuire and Turkewitz (1979) distinguished between the objective (physical characteristics) and effective (organismic variables) intensities of a given stimulus. Stimulus intensity is a complex construct and not readily identified in a single modality or by a single physical characteristic. It has been defined in dynamogenic terms (Grice and Hunter 1964) as a dimension dependent on an organism's adaptation level (Helson 1964). Helson's mathematical analysis of a stimulus includes its physical characteristics, the state of the organism (including its degree of maturation and developmental level), and other contextual factors, a crucial dimension that Lerner (1989) has termed developmental contextualism. In the phenomenon of imprinting, Moltz (1963) invoked the A/W idea and hypothesized that chicks would imprint to withdrawing objects and not to those which approached. Whereas his data did not support this idea, Bengtson's (1983) analysis of the complexity of visual stimuli offers an explanation of Moltz's failure. Bengtson showed that, in imprinting, the intensity of the visual stimulus is a complex function of its angular speed and distance from the eye. Large imprinting objects, then, are not necessarily more intense than smaller ones. What was large or small to Moltz may not have been so to his chicks. Schneirla (1959, 1965) discussed A/W responses in many species and to many types of stimuli. For example, his 1959 paper "cited the apparent approach to moonlight reflecting from the surf by newly hatched loggerhead turtles at night, the proneness of certain lizards to approach green as opposed to other spectral hues and to approach figures with smooth outlines rather than others with broken outlines" (Greenberg and Haraway 2002, p. 64). Greenberg and Haraway's discussion of A/W shows it is still an important critical idea in comparative psychology.

## A/W Theory Today

With a single exception – Wolfgang Schleidt's (Schleidt et al. 2011) continued rejection of

Schneirla's interpretation and his continued support of the Lorenzian ethological interpretation of the Hawk-Goose phenomenon (that young birds flee from a hawk like figure because of an innate recognition of its predatory nature, rather than Schneirla's (1965) analysis that the shape of a looming predator is a more intense visual stimulus than is the shape of a looming non predator such as a goose) – it is a curious twist of history that the A/W concept has absolutely vanished from use in the animal behavior literature. Of course, Schleidt himself is an ethologist. However, despite a cautionary comment made by the influential developmentalist John Bowlby (1969) soon after Schneirla's (1965) last extended statement of the A/W concept, that "the extent of its applicability remains unknown" (p. 149), interest in the idea has persisted among developmentalists of all stripes (Hood et al. 1995). While many invoke the concept few acknowledge Schneirla's influence, as noted by Turkewitz (1987):

By the time his [Schneirla's] viewpoint had penetrated the realm of developmental psychology it had become, arguably, the dominant position in developmental psychobiology. As such, it tended to be treated by developmental psychologists as a product of the *zeitgeist* or as part of general lore, thus, not requiring attribution. (p.369)

A sampling of contemporary developmentalists working with A/W as formulated by Schneirla are:

**Margaret Sullivan:** work from her research group (e.g., Lewis et al. 2015) has often focused on aspects of emotional behaviors – anger, for example, as expressed by infants in response to blocked goals. This phenomenon is understood to be an approach-related affect. Their work is consistent with "Darwin's observation that anger leads to behaviors in overcoming obstacles to regain a goal while sadness is a withdrawal emotion as measured related to movement away from the goal. These differential action tendencies are supported by facial behaviors, body activity, and physiological responses such as heart rate and cortisol increases..." (Lewis et al. 2015, p. 1553). Schneirla (1959, 1965), too, indicated that A/W responses apply to the entire organism,

from its overt behavior to its covert physiology and neurology.

**Nathan Fox:** Fox's prolific group often focuses on physiological correlates of temperament (e.g., Helfinstein et al. 2012). Citing earlier work on several animal species they note that biphasic "tendencies across many species suggests that there may be neural circuitry common to many species that is involved in these behaviors...[M]ore recent work has extended these findings on approach by focusing on the neural architecture moderating approach-related behavior. Most recently, this work has mapped the relations between individual differences in human temperament and individual differences in neural circuitry function" (p. 818).

Much contemporary work in development, emotion, and temperament frequently refers not to "withdrawal," as in the Schneirla A/W formulation, but rather to "avoidance." This focus is the case in the Helfinstein article cited above and others such as Blair et al. (2004), who do not cite Schneirla, although they purport to study approach/withdrawal in preschoolers. They use *avoidance* and *withdrawal* interchangeably. Schneirla was quite clear that his use of *approach* is not the opposite of *avoid*: "Confusion is indicated when the term 'approach' is combined with 'avoid,' avoid' as if these were opposite concepts for motivation. ... Seeking and avoidance are of a higher evolutionary and developmental order than approach and withdrawal, and these terms should not be mismated" (Schneirla 1959, p. 298).

Another example of this point is Eliot (2006) who does cite Schneirla and thus, presumably, intends to be studying A/W. The term "withdrawal" never appears in his paper and it is clear that he is equating it with "avoidance." Citing Schneirla (1959), he comments that some have characterized "approach avoidance behavioral decisions as the most critical adaptive judgments that organisms have had to make in the evolutionary past, and it is likely that this adaptive function is the reason that approach-avoidance process are witnessed across animate forms of life..." (p. 113).

Lerner (1989) maintains that when Schneirla and his colleagues articulated the concept of

probabilistic epigenesis, they were laying the groundwork for modern developmental theories including the life span perspective in general. This essay is my attempt to outline the essentials of what is surely the most ambitious theoretical endeavor in comparative psychology, past and present. Schneirla began his theory building process in the early stages of his writing. Indeed, his now classic book, *Principles of animal psychology*, co-written with N. R. F. Maier (1934), contains the seeds of the theoretical ideas described in this essay. The principles are postulated to be universal, applying equally to humans and non-humans alike. The “theory,” incomplete as it is, has influenced many researchers across numerous spheres of psychology. Although he was a comparative psychologist, the persistence of his ideas in developmental psychology attests to its enormous significance.

<sup>2</sup>Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

## Synonyms

Core number system; Numerical cognition; Numerosity

## Definition

The approximate number system (ANS) is a core cognitive system of numerical processing that governs animal and human nonsymbolic numerical representations. Weber’s law underlies the ANS, in which performance in discriminating set sizes increases as the ratio between sets also increases.

## Introduction

The ability to perceive, discriminate, store, and represent numerical information supports a host of everyday human behaviors and makes possible engineering feats that drive many of our technological innovations. Of relevance to the current chapter, engineers, astronauts, banking institutions, store clerks, and elementary math students base their simplest and more complicated calculations and numerical processing on a core system of number that is shared among human individuals as well as across a wide range of nonhuman species. Nonhuman animals (hereafter animals) also are sensitive to the quantitative and numerical nature of stimuli in their natural world, although they lack the more advanced forms of numerical

and quantitative processing that constitute a formal system of mathematics. But, even their more limited sensitivity to numerosity is important to many aspects of survival (e.g., foraging, predation, reproduction). To give an example from foraging behavior, discrimination of the largest amount of food from multiple options likely contributes to increased fitness, placing a premium on the ability to discriminate based upon quantity and perhaps even numerosity.

## The Approximate Number System

The core system of number processing is commonly referred to as the approximate number system (ANS) and has been proposed to govern animal and human nonsymbolic numerical representations (see Brannon and Roitman 2003; Cantlon et al. 2009; Gallistel and Gelman 2000, for reviews). A central feature of the ANS is that it follows Weber's law, which states that the degree of discriminability of stimuli is consistent provided the *relative difference* of the stimuli remains the same even as their absolute magnitudes change. The approximate, rather than exact, representational fidelity of true sensory experiences is another feature. Thus, quantities are represented inexactly, and the ability to discriminate any two quantities is a function of the ratio of those quantities to each other, rather than a function of the absolute sizes, numbers, or amounts (see Gallistel and Gelman 2000). Two important behavioral signatures of the ANS are the distance effect and the magnitude effect, both of which combine to generate what is often called the ratio effect. The distance effect reflects that the ability to discriminate between two sets or arrays varies as a function of the absolute difference between sets (e.g., it is easier to tell 10 coins from 5 than telling 10 coins from 8). The magnitude effect reflects that, in general, larger magnitudes or quantities are harder to distinguish from each other than are smaller magnitudes even if the difference is the same (e.g., it is harder to tell 10 coins from 9 compared to telling 4 coins from 3). The ratio effect therefore reflects Weber's law in showing that at a constant ratio, there is a constant degree of

discriminability (e.g., one will be as good at telling 4 coins from 5 as they are at telling 8 coins from 10, assuming the ANS is engaged in estimating the numbers of coins). For an example relevant to animal foraging, a ratio of 2:1 (8 berries vs. 4 berries) is easier to discriminate (i.e., reflected in higher accuracy and faster response times) than a 3:2 ratio (12 berries vs. 8 berries), despite the fact that the absolute difference in each array is the same – 4 berries.

## Behavioral Evidence for the ANS: Quantity Judgments

Comparative tests of numerical cognition often are assessed through relative quantity judgment tasks that present an individual animal with two or more arrays that vary in quantity (size, numerosness, or volume), quality (relative degree of preference), or sometimes both. When food stimuli are used, little to no training is required, and stable response patterns in terms of subjective food preferences as well as objective measures of quantity discrimination abilities are established. For example, when a female chimpanzee named Lana was presented with two quantities of cereal, she reliably chose the larger quantity of each comparison. And, in accordance with the signature size effect of the ANS, Lana's performance decreased when both sets were close to the upper limit of the total possible number of cereal pieces (10) and when the ratio between sets was closer to one (e.g., 8:9 was more difficult than 6:9; Dooley and Gill 1977). Tests of relative food quantity discrimination have now been given to a wide range of animal species, underscoring the adaptive value of quantity discrimination capacities, and in many cases ratio effects are evident.

Animals also have demonstrated proficiency in similar quantity discrimination tasks presenting only one food array at a given time. For example, orangutans (Call 2000), chimpanzees (Beran 2001, 2004), and capuchin monkeys (Evans et al. 2009) excelled at selecting the larger of two food quantities even when only one quantity was visible at a given time (either by presenting the subject with one entire array prior to the other

or by sequentially adding food items to one array at a time). Performance patterns revealed ratio effects characteristic of the ANS, and importantly, these results suggested that primates could represent numerical information similar to human adults in addition to the use of perceptual mechanisms. Similar performance patterns are evident in work with a variety of nonhuman primate species (e.g., Addessi et al. 2008; Hanus and Call 2007).

### **Behavioral Evidence for the ANS: Numerosity Judgments**

Relative numerosness tasks, unlike relative quantity judgment tasks, specifically control for nonnumeric cues that may lead an animal to respond based upon some other quantity dimension separate from number (e.g., size). These tasks are unique in that only true numerical (i.e., cardinal) properties can be used to guide responding rather than other nonnumeric cues (e.g., surface area, total volume, presentation speed, auditory cues, etc.). In perhaps the clearest example of such a task, Brannon and Terrace (2000) presented rhesus macaques with a computerized experiment depicting randomly generated stimulus arrays and trained the monkeys to sequence the numerosities 1 to 4 in ascending order while controlling for size, shape, and color of the items within arrays. In unreinforced transfer trials, monkeys responded to the numerosities 5 to 9 in ascending order. Importantly, performance patterns including accuracy and latency matched those of human adults in terms of distance and size effects of the ANS for both sets of numbers, even in the novel transfer trials. In a similar study, pigeons learned to sequence visual arrays of items in the numerical range of 1 to 7, with smaller numbers (and larger distances between the numbers) leading to higher performance rates in line with the predictions of the ANS (Emmerton et al. 1997). Subsequent research based on this task with other species including capuchin monkeys (Judge et al. 2005), a baboon and squirrel monkey (Smith et al. 2003), and lemurs (Merritt et al. 2011) revealed similar performance patterns governed by ratio effects.

As demonstrated above, carefully controlled numerosity tasks afford an advantage over food choice paradigms in that a variety of nonnumeric cues can be carefully controlled, and one is not faced with the concern that animals may find total amount of food more salient than the larger number of food items. Thus, efforts to automate and control sequential presentation tasks also have been developed. For example, Beran (2007) presented a computer task with two digital “containers” to rhesus monkeys into which digital items were “dropped” with the task objective to choose the container that received a greater number of items. The monkeys tracked and selected the larger of the two numerosities despite the fact that presentation duration (i.e., how quickly the items were added to the containers) and surface area (i.e., size of the falling items) were controlled. Monkeys showed clear evidence of ratio effects in all tests.

How do these comparative results stack up to human adult performance? The evidence indicates that the ANS is at play similarly in both human and nonhuman primate numerosity judgments, and direct comparisons of monkey and adult performance on similar tasks provide further support. For example, when human adults are prevented from counting via speeded presentation of stimuli or by use of articulatory suppression (e.g., Agrillo et al. 2016; Whalen et al. 1999), they demonstrated similar performance patterns to nonhuman primates in terms of the degree to which they respond on the basis of the ratio between sets. Cantlon and Brannon (2007) presented rhesus macaques and human adults with a computerized nonverbal addition task with the objective of adding together two dot arrays. These arrays were sequentially presented and subjects then selected between a dot array that represented the correct numerical sum and a foil dot array with the wrong answer. Although humans outperformed monkeys on the addition task, both adult and monkey performance was ratio dependent. As the ratio between the numerical sum and the foil approached one, performance in terms of accuracy decreased. These direct comparisons of animal to adult performance using identical methodology lend further support for continuity

in numerical processing devoid of human-unique experiences, culture, and linguistic processing and specifically a system that relies upon analog-numerical representations.

### Controversy: One Number System or Two?

There is little controversy surrounding the existence of the ANS as a core system of number. Although the ANS and its effects are well understood and accepted in the numerical cognition literature, there is also a claim for the existence of a second system for representing numerosity that is size-limited (typically described as four items or less) but that precisely represents small sets of discrete items. This second system, often referred to as the object file system (OFS), is described as a parallel individuation system that is limited in its ability to discriminate and estimate sets greater than four due to demands on attention and working memory (Feigenson and Carey 2005). Evidence for the OFS emerged from the developmental literature with young children and infants who demonstrated elevated performance patterns in response to small sets in comparison to large sets (containing more than four stimuli; e.g., Feigenson et al. 2002). However, other reports suggest that the ANS appears to be the main system underlying discrimination performance with little evidence for the OFS (e.g., Cantlon et al. 2010).

Comparative studies provide some support for elevated performance with small sets of less than four stimuli (fish: Agrillo et al. 2014; birds: Garland et al. 2012; amphibians: Krusche et al. 2010; primates: Hauser et al. 2000). For example, Hauser et al. (2000) presented semi-free ranging macaques with a two-choice discrimination task in which apple pieces were added to two buckets and the monkeys then selected the desired bucket (and presumably larger quantity of food). Monkeys successfully discriminated comparisons with small numerosities (1 vs. 2, 2 vs. 3, 3 vs. 4, 3 vs. 5) but failed at comparisons containing sets

with a larger number of items (4 vs. 5, 4 vs. 6, 4 vs. 8, 3 vs. 8). These results stand in contrast to a large number of primate studies demonstrating evidence of ratio effects with no evidence of a super-precision with small sets (e.g., Barnard et al. 2013; Beran 2001, 2004, 2007; Cantlon and Brannon 2007; Hanus and Call 2007; Nieder and Miller 2004).

In a recent comparative study, Beran and Parrish (2016) adopted a procedure used with human adults to assess the object file system in capuchin monkeys. In the original human study by Choo and Franconeri (2014), adults were presented with a computerized relative discrimination task comparing two sets of dots to one another followed by a same/different task in which they had to designate two sets as containing an identical number of dots or not. Both sets were either small (3 dots against 1, 2, 4, or 5 dots) or large (30 dots against 10, 20, 40, or 50 dots). Adults demonstrated faster response times when comparing the small sets versus when comparing the large sets despite the identical ratios. Capuchin monkeys did not show the same “super-precision” with small sets compared to large sets, with performance instead dictated by the ratio between dot arrays (Beran and Parrish 2016). A key feature of the comparative task was that it was the first formal study of numerical cognition given to these monkeys, and thus they had not received extensive training or former experience making these types of numerical judgments (see Bisazza et al. (2014) for a greater discussion on how training may lead to an overreliance on the ANS).

The debate regarding the existence of two core systems of number or one is ongoing, but comparative research definitively indicates that the ANS underlies much of our own numerical discrimination abilities as well as those of other animal species. It is also possible that a system equipped to deal with small sets with super-precision may be a result of human-unique learning experiences (e.g., Hyde 2011) or a necessary feature for tracking small sets of moving objects (Franconeri et al. 2007). Such a size-limited

system as the OFS for processing small numbers may be used by some species under certain conditions.

## Summary

The ANS is a hallmark feature of animal cognition. It underlies nearly all reported instances of numerical or quantitative judgments by species ranging across the spectrum of those that have ever been tested by comparative psychologists. The ANS is evident across sensory modalities (visual, auditory, etc.), and for discrete and continuous quantities, although its primary empirical assessment has been with discrete, visual stimuli. Behavioral studies such as those outlined in this article suggest an ontogenetic and phylogenetic continuity in numerical and quantitative processing. A consensus has emerged that the ANS supports and perhaps underlies advanced mathematical and numerical representations that emerge in human development and with formal education.

## Arabic Numerals

Travis R. Smith<sup>1</sup> and Michael J. Beran<sup>2</sup>

<sup>1</sup>Georgia State University, Atlanta, GA, USA

<sup>2</sup>Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

Nonhuman animals are implicitly sensitive to numerosity that does not require symbolic verbal representation of the numbers and does not require a counting repertoire (e.g., an analog magnitude system). In addition, with training, animals can demonstrate sensitivity to numerosity in a more precise manner that is aided by symbolic representation of numbers – such as Arabic numerals. Animals' use of numerals indicates a sense of “cardinality” regarding numerosity, and is a central feature of more advanced mathematical cognition. Comparative numerical cognition research has focused on whether animals can use Arabic numerals in a similar way to how humans use numerals, and what that may tell us about the basic cognitive processes that underlie the symbolic understanding of numerosity.

One approach to evaluating whether animals can represent numerosity symbolically is to have them appropriately match a numeral to some number of items (i.e., provide a cardinal label such as a numeral or other symbol for the perceived number). For example, Boysen and Berntson (1989) reported that a chimpanzee could identify the number of objects in her environment and point to the corresponding Arabic numeral. She also spontaneously demonstrated numerical representation through addition by correctly identifying the number of objects arranged in different locations and summing their numerosity before pointing to the numeral that indicated the summed total. Matsuzawa (1985) also showed that a chimpanzee could apply Arabic numerals as labels for sets of one to six items even when those items varied across trials. Pepperberg (1987) similarly demonstrated that the parrot Alex could report Arabic numerals vocally as the labels for sets of items and accurately report the summation of two sets.

Alternatively, animals can demonstrate the understanding of number cardinality by having them identify or collect an appropriate number of items to match a given Arabic numeral. This kind of task has come to be called “constructive” enumeration, because subjects need to use the numeral to guide subsequent collection efforts, presumably while enumerating items that have been collected and tracking whether that enumeration matches the Arabic numeral value. Rumbaugh et al. (1989), for example, demonstrated that the chimpanzee Lana could learn through successive training stages to see an Arabic numeral on a computer screen, and then use a cursor to collect boxes onscreen one at a time, until she had collected a set equal to that represented by the numeral. Lana and another chimpanzee, Mercury, learned to do this for up to the numeral 7 (Beran and Rumbaugh 2001). Xia et al. (2000) showed that pigeons could make the same collection responses by pecking a key an equivalent number of times to the Arabic numeral-like symbol presented on it. Like chimpanzees, pigeons were successful up to the numeral 6. However, in all of these cases, an interesting pattern emerged whereby larger set sizes were more difficult for subjects to match in their collections or pecks, a result that aligns with the idea that numerosity is represented inexactly by nonhuman species, with increased variability in those representations that follows Weber’s law. Specifically, Weber’s law states that stimuli must differ by the same proportion for individuals to maintain the same level of discrimination performance (e.g., discriminating three from six items is the same level of difficulty as discriminating five from ten items).

Experiments requiring the matching of numerals to sets-of-items and sets-of-items to numerals provide evidence that animals can establish symbolic recognition of a number’s cardinal value. Further research has established that animals can also symbolically recognize numbers’ relative values (i.e., their ordinal value). Washburn and Rumbaugh (1991) demonstrated that rhesus monkeys (*Macaca mulatta*) would choose the larger numeral in a set of numerals where the number of pellets earned matched the value of the numeral, even in probe trials with a novel set of numeral arrangements that had never been presented

before. Harris et al. (2010) expanded upon this to show that when facing a novel pairing of an array of dots to a numeral, macaques would spontaneously choose the higher valued option in either form. Olthof et al. (1997) presented squirrel monkeys with Arabic numerals in a manual task that involved the numerals indicating how many food items were hidden underneath the cards on which they were written. After the monkeys learned to choose the larger numeral values, they were presented with combinations of numerals to see if they could sum those values to determine the larger overall food amount from the two sets of numerals (in these tests, the monkeys could be shown 2 numbers vs. 2 numbers, 1 number vs. 2 numbers, and 3 numbers vs. 3 numbers). The monkeys generally selected the largest total amount of food given the combinations of numerals they saw in the response options, even when they sometimes had to choose a set with more overall food but not with the individually largest-value numeral. For example, they chose  $3 + 3$  over the numeral 5 in some cases. These results suggest that monkeys and pigeons can map numerals to a set amount and that this symbolic representation includes a generalized understanding of the relative ordinal numeral value. However, this transfer of ordinal recognition of numerical value did not generalize to the number “0” (i.e., cardinally the absence of an item or ordinally the value below 1) in chimpanzees (Biro and Matsuzawa 2001). The parrot Alex also failed to spontaneously recognize 0 in its ordinal position, although the parrot did recognize that 0 corresponded with “none” (Pepperberg 2006).

Arabic numerals also can be used by animals as information symbols for things that they must do. For example, Harris and Washburn (2005) showed the monkeys learned that Arabic numerals found inside a computerized maze indicated how many times that arm of the maze should be investigated because the numeral represented the number of rewarded runs of that arm of the maze. Comparative interest in number symbols such as Arabic numerals also goes beyond the desire to understand the processes underlying sensitivity to numerosity. The utility of such numeral knowledge can aid in research into other cognitive

processes such as executive functioning and planning strategies in animals. Washburn (1994), for example, demonstrated that an array of numerals can produce a Stroop-like interference effect. Washburn trained macaques to select the larger of two arrays of items onscreen. In baseline trials, the stimuli making up each set were nonnumerals, and thus monkeys faced no possible interference. However, when numerals were used, they either operated to aid the discrimination (congruent trials) because the set with more stimuli also consisted of the larger numeral items (e.g., an array of four numeral 3s vs. an array of two numeral 2s) or they operated to create potential interference (e.g., an array of four numeral 2s vs. an array of two numeral 3s). Washburn showed that performance was better when the number of numerals was congruent with the symbolic value of the numerals than when it was incongruent, a result that nicely suggested Stroop-like interference. In another approach to using numerals to assess broader cognitive capacities, Kawai and Matsuzawa (2000) studied planning abilities in chimpanzees when they had to sequence numerals. In that task, the chimpanzees had to select Arabic numerals in ascending order on a computer screen, with the key manipulation being that the numerals did not stay onscreen but were covered after being presented only briefly. Given this brief presentation, the chimpanzees had to rapidly discern where each of the numerals was located and then remember the necessary sequence to touch them all even after they were occluded. Thus, the sequencing of Arabic numerals allowed an assessment of working memory span and planning in chimpanzees.

To summarize, the use of Arabic numerals as discriminative stimuli has contributed many interesting findings in the comparative literature, both for “formal” studies of numerical cognition and for other areas of cognitive processing and behavioral discrimination. These findings are robust in that they have been observed in a variety of species and across a variety of tasks. Furthermore, these comparative data are often in agreement with results found in humans, particularly younger children in the case of numerical cognition research. Such results suggest a shared evolutionary mechanism that mediates symbolic discrimination across species, perhaps especially for

magnitude and quantitative information. Arabic numerals acquire meaning for animals, and can be used as important tools for understanding symbolic representation in other species.

## Arbitrary Stimuli

Hakan Çetinkaya

Department of Psychology, Faculty of Languages, History and Geography, Ankara University, Ankara, Turkey

## Synonyms

Generic; Neutral; Ubiquitously selected stimuli

## Definition

An arbitrary stimulus is an arbitrarily chosen cue paired with a biologically significant event (e.g., Unconditioned stimulus (US)). It does not have to share any inherent relationship with the US.

## Introduction

Definitions of Pavlovian conditioning from the general process view often pertain to forming associations between initially unrelated events. Usually, a cue that is neutral or arbitrary in relation to the US is paired repeatedly with the US in a certain temporal proximity. As a result, the cue alone comes to elicit conditioned responding. Conditioning is then identified by an increase or decrease in potential of responding to the conditioned stimulus (CS). The main premise of general process approaches to conditioning and learning is that all forms of learning could be explained in terms of a relatively modest number of general principles, and this popular description of Pavlovian conditioning reflects some of the important principles of how conditioning occurs. For sure, the search for general principles is one of the most important aspects of any scientific venture, and the general process view of Pavlovian conditioning has provided a great deal of knowledge about the principle mechanisms of conditioning and learning. Pavlov (1927) identified some of the major behavioral phenomena such as delayed conditioning, inhibition of delay, extinction, and spontaneous recovery in his laboratory. He noted that intense stimuli made more effective CSs than less intense ones. In addition to the stimulus intensity, he emphasized the role of CS modality in conditioning. For instance, tactile and auditory stimuli were more effective CSs than visual or thermal stimuli in the case of salivary conditioning with dogs. Thorndike (1911) had already dared to propose the Law of Effect to formulate the mechanism of instrumental behavior when Skinner (1938) characterized his own general process of learning based on schedules of reinforcement and shaping. According to Skinner, any arbitrary associative link could be formed between a response and the outcome with the same ease. These early efforts to establish general laws or principles of learning were followed by more recent researchers. Each of them contributed towards the betterment of the general theories of learning by revising or reformulating the previous ones. Kamin's (1969) demonstration of blocking effect is a turning point in the endeavor; his work indicated that the temporal contiguity accounts of

Pavlovian learning for the acquisition of conditioned responses were insufficient, in fact the paradigm might be more about contingency rather than contiguity. In other words, what a CS tells about the occurrence of the US should be more important than whether they are in temporal proximity. According to Kamin (1969), when we come to the second phase of the blocking procedure, the US has already become fully associated with the CS, thus in the presence of the same CS, the US is ineffective. Because the US is highly expected and no longer surprising now, there will be no more room for further increase in associative strength for another CS in spite of its temporal contiguity with the US. Thus, “the necessary and sufficient conditions” for the establishment of CS–US association needed to be investigated.

Rescorla and Wagner (1972) formulated an acquisition theory of learning focusing on the circumstances producing Pavlovian conditioning. The theory was able to offer an explanation for how a neutral stimulus gains associative strength from one trial to the next as the function of US expectancy by considering the summed associative strength of all cues present during that trial. Moreover, it was compatible with various learning phenomena such as blocking, overshadowing, overexpectation, and contextual conditioning. In the model, although CSs do not have to be purely neutral, they are always something arbitrary. The model grants the differences among CSs in terms of differences in their salience; however, in the original version of the model, the salience of a CS is constant and does not change during training. Although later on Wagner and Rescorla (1972) allowed that the effectiveness of CS could vary by factors other than its intensity, they did not use it any further than to explain the CS-pre-exposure effect. The attention-based models of conditioning (e.g., Mackintosh 1975; Pearce and Hall 1980) predominantly focused on the effectiveness of a CS in terms of the amount of attention it governs. For example, Mackintosh (1975) suggested if a CS predicts the occurrence of the US better than other stimuli present in the situation, its associability, and hence its effectiveness as a CS, will increase. Therefore, the effectiveness of a CS is the measure of its relative predictive strength in

regard to the other CSs present. The model is based on the change in associability of the CS through experience. These and other following models such as the SOP and AESOP models (Wagner 1981; Wagner and Brandon 1989), the comparator hypothesis (Stout and Miller 2007), the temporal coding hypothesis (Savastano and Miller 1998), and Rate Expectancy Theory (Gallistel and Gibbon 2000) treated a CS as an arbitrary stimulus.

Traditional accounts of conditioning included parameters such as stimulus salience, intensity, and discriminability in their analyses; however, they implicitly or explicitly agree with the notion of stimulus equivalency (Johnston 1981). According to the principle of stimulus equivalency, stimuli are generic events; hence, any two events could be associated with equal ease. Therefore, conditioned responses would develop regardless of the preexisting relations between the conditioned stimulus (CS) and unconditioned stimulus (US). Also, according to traditional general process views, the specific biological constraints experienced by species from different ecological niches that arose via evolution were insignificant in the analysis of behavior. This view calls forth the idea that the CS, by definition, is “neutral,” and it has no inherent effect on conditioning. Thus, the CS may be chosen arbitrarily with respect to the US. As Pavlov once assumed, any cue an animal could sense could be used as a conditioned stimulus for every response (Lakoff and Johnson 1999). The general process-based view of conditioning and learning made remarkable contributions to our understanding of the mechanisms of various learning phenomena. However, it has not said much about functional roles that conditioning plays in the lives of animals (Domjan 2005). This mechanistic-associative view has changed as behaviorist principles have undergone significant revision, particularly in light of findings from functional perspectives on learning.

In their long evolutionary histories, species have evolved necessary machinery to associate the co-occurrence of naturally occurring CSs and USs. In contrast to arbitrarily chosen cues, ecologically relevant cues are readily associated with their

resulting counterparts. Such examples shed light on the ultimate causes of learning mechanisms. For example, rats were able to associate audiovisual cues with a foot shock but not so with the illness; moreover, they were able to associate taste cues with illness but not so with the foot shock (Garcia and Koelling 1966). Similarly, Foree and LoLordo (1973) found that pigeons predominantly use auditory cues as discriminative stimuli for avoidance behavior as opposed to visual cues. What if an arbitrary CS reliably precedes the biologically significant US? Animals indeed learn to associate an arbitrarily chosen CS with the US. According to the Behavior Systems Approach (Timberlake and Lucas 1989), a conditioned stimulus (CS), even though it may be an arbitrary CS, is integrated into the behavior system that is activated by the US through the conditioning process. For example, an unpleasant US such as presentation of a brief foot shock activates a defense behavior system which generally includes unconditioned species typical defense reactions (e.g., jump). An arbitrary CS, which may be a brief tone or a light presented in the experimental chamber, is paired with the aversive US repeatedly until it reliably signals occurrence of the US. The CS-alone tests trials evince, by an increase in animal's immobility (e.g. freezing), that the CS acquired conditioned properties and became an integral part of the animal's defense behavior system. The nature of the resultant CR is determined by the behavior system relevant to the US involved. For that reason, the CR is not jumping but rather a freezing response. The ease of learning a particular task depends on the extent to which the conditioned stimulus is relevant to the behavior system that is activated by the US. In natural circumstances, ecologically relevant CSs which are already parts of the relevant behavior system reliably precede the occurrence of USs. Thus, Timberlake's (1994) pursuit to integrate stimulus and response factors into a general theory of learning has been well received by the scientific community. In line with the rise of functional approaches to learning, there has been growing interest in examining the ecological relevance of Pavlovian conditioning. For example, Domjan et al. (2004) applied functional approaches to better understand how Pavlovian conditioning interacts

with the preexisting organization of behavior in an animal model of sexual conditioning.

In conclusion, the general process theorists held that there is a set of general principles applicable to all learning; also, they believed that all examples of learning are manifestations of an underlying general process. This focus on searching for general mechanisms responsible for conditioned behavior surely advanced our understanding about various learning phenomena such as acquisition, extinction, external inhibition, recovery from extinction, stimulus generalization, stimulus discrimination, latent inhibition, conditioned suppression, conditioned inhibition, and blocking. The majority of these phenomena have been observed in laboratory settings by employing stimuli that are arbitrary with respect to what animals might experience in their natural environment. A complementary approach, which has yielded important additional insights into how conditioning works, focuses on functional and ecological relationships between animals and how they learn (Domjan et al. 2004).

## Arboreality

Susannah K. S. Thorpe and Jackie Chappell  
University of Birmingham, Edgbaston,  
Birmingham, UK

## Introduction

Arboreality simply means living in the trees. There are numerous species that live in trees for all or part of their lives, including a wide range of rodent species, monkeys and great apes, koalas, sloths, many species of birds (such as parrots), and lizards like chameleons and geckos. Some animals live both on the forest floor and in tree crowns, whereas others, like Sumatran orangutans, are almost exclusively arboreal, rarely descending from the tree canopy. Arboreality imposes unique cognitive demands on animals because of the physical structure of the environment: trees and their branches form a discrete and discontinuous surface on which animals can move, and the risk of falling means that animals need to choose safe supports that can bear their weight in order to travel safely. In addition, food may be patchily and unpredictably distributed in three-dimensional space, so the cognitive demands of finding and processing food and of creating safe and comfortable places to sleep are greatly enhanced in arboreal compared to terrestrial habitats. Finally, forest environments (particularly those in the tropics) are often highly dynamic environments, with rapid growth and decay of trees, so that the physical environment may change in structure within an individual's lifespan. However, the cognitive challenges of arboreal life will vary among different taxa, according to their body size, mode of locomotion, and the part of the forest canopy that they need to access and move around.

Many animals that exploit both the forest floor and forest canopy need to climb, sometimes large distances, to get into the forest canopy, which requires them to oppose gravity. This is highly physically demanding, but is probably not cognitively demanding because the supports are not

compliant (flexible) – either because they are large (like tree trunks) or because the weight of the animal stabilizes the support (e.g., when chimpanzees climb thin vines or humans climb ropes). This allows the animals to rely on stereotyped, preprogrammed movements, which are cognitively simple and relatively easy to learn (Hunt 2004). Similarly, since forest-living bird species such as the scarlet macaw (*Ara macao*) can fly, they face fewer challenges accessing the forest canopy than arboreal mammals. In contrast traveling within tree crowns for mammals and birds can be both physically and cognitively demanding because forest canopy consists of a three-dimensional mesh of branches and vines that vary in their connectedness, flexibility, and continuity (Thorpe et al. 2009). For small-bodied animals, the gaps between branches can be very large in proportion to their body size, requiring large leaps to progress. For large-bodied animals, not all of the available supports will be strong enough to support their weight, leading to a risk of falling and potential injury or death. Many of the available weight-bearing supports may also deflect underneath their weight, making it difficult for them to predict how the support will behave when they load their weight onto it and requiring them to adjust their movement moment-by-moment as supports are found to be more or less compliant than estimated (Hunt 2004). These issues mean that large-bodied arboreal animals need to choose the supports they use carefully and therefore raise interesting questions about how much arboreal animals understand about the physical properties of their environment.

For many animals, the most challenging part of the forest canopy is called the “terminal branch niche.” This refers to the highly flexible branches at the periphery of tree crowns which bend substantially under the animal’s weight and vary enormously in their properties, making simple learning strategies ineffective. Despite the increased risks of falling in the terminal branch niche, it is one of the most desirable parts of the forest canopy for arboreal animals because it is where fruits tend to be abundant and where the narrowest gaps between tree crowns exist for animals that travel at height. Being able to predict

how flexible branches and lianas will behave under their weight is critical for the animal to ensure its safety and to minimize its path length to optimize the ratio between its daily energetic cost of locomotion and the energy it is able to consume. This becomes particularly cognitively challenging during long-distance arboreal travel where the animals ideally need to plan routes at least several steps ahead, to ensure they will not have to retrace their steps or take lengthy detours when they find gaps they cannot cross or supports that are not strong enough to take their weight.

### Cognitive Challenges of Arboreal Environments

We have outlined some of the challenges that arboreal environments pose for the animals that inhabit them. However, why might these challenges require specifically *cognitive* solutions, rather than the evolution of other kinds of behavioral adaptations, such as instinctive behavior or forms of associative learning? While there is considerable debate about the precise definition of the term “cognition,” there is reasonable consensus that it involves collecting, processing, and making decisions on the basis of information from the environment (see Shettleworth 2010). The key feature of cognition is therefore that it is flexible, allowing the animal to respond appropriately, even in novel situations. This is important in arboreal environments, because they tend to be complex and dynamic, showing substantial variability over both time and space. This means that a fixed or limited repertoire of responses is unlikely to be adequate, as the “appropriate” response is likely to change frequently (Chappell et al. 2012).

For many years, it was argued that ecological factors were likely to have driven cognitive development in primates, either because of the demands of locating unpredictable, spatially distributed food resources in tropical forests (Milton 1981) or because of the demands of dealing with a complex physical habitat (the “Technical Intelligence Hypothesis”: Byrne 1997). Subsequently, the research focus has shifted to social drivers of primate intelligence (the “Social Brain

Hypothesis”: Dunbar 1998). However, a recent, large, and robust meta-analysis of data on a range of primate species has suggested that brain size (and therefore, it is assumed, intelligence, but see Healy and Rowe (2007) for a critique) in primates is associated with diet, not sociality (DeCasien et al. 2017). Certainly, a variety of ecological factors associated with the complexity of arboreal life are likely to have been important for many arboreal animals, not just primates. Nevertheless, some of the largest animals to rely on forest canopy are the great apes: orangutans (*Pongo* sp.) are almost exclusively arboreal, and chimpanzees (*Pan* sp.) and gorillas (*Gorilla* sp.) exploit forest canopy extensively, particularly during the fruiting season. Their size means that they need to select supports for locomotion and nest building very carefully in order to avoid potentially lethal falls. This means that they may benefit from representing problems in a more abstract way, so that they can potentially evaluate the outcome of alternative actions mentally rather than physically, possibly planning such actions more than one step ahead. However, the behavioral adaptations of great apes and other arboreal species include elements of instinctive and learned behavior, alongside more cognitive elements. Untangling these inputs is difficult, but we can focus on flexible and contextually appropriate behavior, in which animals respond to the particular suite of problems with which they are faced.

In this contribution, we flesh out these possibilities in relation to great apes and also explore whether other species that live in arboreal habitats might also have evolved advanced cognitive abilities linked to their environment. We predict (**P**) that some arboreal animals, particularly the large-bodied ones that use the terminal branch niche or travel at height, can (**P1**) detect and reason about the properties, physical behavior, and affordances of arboreal supports and (**P2**) also about the predictable physical effects of their own actions. We suggest they might be able to (**P3**) evaluate routes in advance of movement and (**P4**) detect new risks or opportunities if supports confound their expectations and exploit these appropriately. We consider these predictions in relation to the cognitive demands of three key components of arboreal life:

nest building, locomotion, and remembering the location of arboreal resources. We then relate these findings to the cognitive needs of intelligent, arboreal species in captivity.

## Arboreal Nest Building

Nests can provide safe arboreal resting spaces for animals, protection from terrestrial predators, thermoregulatory advantages, and/or freedom from biting insects found at lower levels (Koops et al. 2012). For birds, nests have a crucial function in the incubation of eggs and sheltering altricial chicks before fledging. Building a safe, structurally sound nest is a complex task, involving selection of an appropriate site and choice of suitable materials. The nest maker then needs to manipulate the materials in relation to each other and the nest substrate to create a nest with enough structural integrity to support its occupants and to withstand movement of the tree and nest in the wind.

All great apes build arboreal nests, both for night-time sleep and for resting during the day (Stewart 2011). Orangutans build nests exclusively in the trees and chimpanzees predominantly do, while western lowland gorillas show the most variable nesting behavior, utilizing unconstructed ground nests as well as fully constructed ground or tree nests (Tutin et al. 1995). Because of the conserved nature of nest construction in great apes, it has been suggested that it evolved in a common great ape ancestor in the Miocene period and is thus likely to have contributed to the origins of great ape intelligence. Although there is likely an innate component to nest building in great apes, it is not an entirely instinctive behavior. Orangutans and chimpanzees are selective about the trees in which they choose to build nests, and research suggests that this relates to the innate flexibility of the wood of different tree species and perhaps to an understanding of the requirement for branches that will exhibit “greenstick” fractures, whereby the end of the branch fractures but does not detach completely (van Casteren et al. 2012). This phenomenon allows strength and rigidity to be built

into the nest by weaving larger branches over a framework of more solid limbs to form a platform, and then smaller twigs are folded over to form a raised rim (van Casteren et al. 2012). In some cases, leafy material is detached and added to the nest bowl to form a sleeping surface (Stewart et al. 2007; van Casteren et al. 2012). These nest types therefore require the ape to have an understanding of the physical properties of different tree species and the effect of their own actions on the branch, meeting predictions **P1** and **P2** above. They also need to organize their behavior in the correct sequence to construct a supportive nest that can bear their weight safely, which indicates an element of planning (**P3**). It has been shown that immature individuals build nests more efficiently and of a higher quality when exposed to nest-building adults which also indicates a role for learning and innovation in the building of nests.

Analogy with arboreal nest building in great apes suggests that some of the nest building behaviors of birds also reflect technical knowledge of the properties and mechanics of the materials they can use to build nests. Arboreal birds' nests vary enormously in their size, location, and structure and in the materials used to construct them (Breen et al. 2016). They can be made from a wide variety of both natural and man-made materials, often with several distinct materials used in one nest, each serving a different function. For example, while the outer part of a nest may be composed of relatively rigid twigs and sticks to provide structural strength, the nest cup may be lined with feathers, mosses, or other soft materials. The use of soft lining materials suggests that, like great apes (Samson and Hunt 2012), the birds have a concept of thermoregulatory needs and/or comfort. Birds' nests also vary widely in complexity, from an untidy pile of material to an intricately interwoven structure. Birds must make a myriad of important decisions, from selecting an appropriate location for their nest, choosing and manipulating appropriate materials, and constructing a secure, structurally sound nest, sometimes coordinating with their mate's construction activity (Healy et al. 2008).

Despite a long history of assumption that nest building by birds is instinctive, evidence is

growing that learning is an important component of nest construction behavior. Breen et al. (2016) have collated a myriad of examples from field-based observations and lab experiments to show that birds modify their behavior in nest site selection as a result of previous breeding success (avoiding previously unsuccessful nest sites but returning to those where they have raised young successfully) and that they vary the materials used according to the nature and risk of predation. Other studies suggest that some bird species may be sensitive to the structural properties of the materials they use. Biomechanical analysis of deconstructed nests showed that female blackbirds *Turdus merula* used significantly stronger and more rigid materials in the outer part of the nest structure compared to the inner part, as appropriate to their differing structural roles (Biddle et al. 2015). Furthermore, in a laboratory setting, male zebra finches *Taeniopygia guttata* preferentially selected nesting material on the basis of its structural properties, as a result of experience of building with different (man-made) materials (Bailey et al. 2014). This sensitivity to context and flexible, appropriate use of materials may fulfil predictions **P1** and **P2**. Although there is currently a lack of research on what guides behavior at each stage of the nest building process, it is possible that there may be an element of planning (**P3**) involved in the order of construction of different components of the nest (Healy et al. 2008).

Since tool use in birds involves similar behaviors (and often similar materials), nest building and tool use may share similar neural foundations (Breen et al. 2016) and represent cognitive abilities on the part of birds to learn (via individual or social learning) about the basic mechanics of the available materials and nest structures and to make decisions about those based on environmental variability. Such a relationship might also apply to nest building and tool use in great apes (Byrne 1997; van Casteren et al. 2012).

## Arboreal Locomotion

Chevalier-Skolnikoff et al. (1982, p. 650) suggested that, at least for orangutans, locomotor

demands were “the single major function for which the advanced cognitive abilities... evolved.” Povinelli and Cant (1995) subsequently suggested that self-concept in orangutans evolved to enable these large-bodied apes to negotiate thin, flexible branches during suspensory locomotion (like arm swinging and brachiation), particularly when crossing gaps in the canopy. They hypothesized that the unpredictable response of compliant weight-bearing structures when weight is transferred onto them, the need for several such structures to support the weight of a single individual, and the erratic orientation of supports together require that orangutans and perhaps other great apes must be able to step outside themselves and imagine how their body and its movements will affect fragile, easily deformable branches and twigs, in advance of movement (Povinelli and Cant 1995; Hunt 2004).

Hunt (2004) tested this theory by comparing the postural and locomotor repertoires of great apes, gibbons and siamangs, and baboons. Nearly 60% of orangutan locomotion relies exclusively on supports that are less than 10 cm in diameter and therefore likely to bend under their body weight (Thorpe et al. 2007), and Hunt found that overall orangutans showed the strongest evidence for positional behavior (posture and locomotion) repertoires likely to elicit a concept of self; however there was also some evidence for lowland gorillas. Although gorillas have long been considered to be largely terrestrial, it is increasingly apparent that they can be highly arboreal (Remis 1999) and that their locomotion is more similar to orangutans than to chimpanzees (Thorpe and Crompton 2006). In contrast chimpanzee positional behavior was far less likely to elicit self-concept, yet they have been one of the most successful in mirror self-recognition tests of self-concept (Gallup 1970; Povinelli et al. 1997). This indicates that the two measures of self-concept might not be causally connected or that self-concept might simply be related to body size rather than the complexity of locomotor and postural interactions between animals and their habitat (Hunt 2004).

Other aspects of arboreal locomotion also seem to require advanced cognitive skills. Tree sway is

a behavior where large-bodied animals, mostly orangutans and gorillas, sway tree trunk or vines back and forth with increasing magnitude to cross a gap in the forest canopy. In a comparison of the mechanical work involved in different types of gap crossing by orangutans, tree sway was found to be less than half as costly as jumping, and an order of magnitude less costly than descending the tree, and crossing the gap terrestrially, indicating that elastic compliance in arboreal supports can be used to reduce the energetic cost of gap crossing (Thorpe et al. 2007).

In order to sway trees to utilize the elastic energy within them, apes must have an understanding of the flexibility of the given tree trunk relative to the size of the gap to be crossed. Juvenile orangutans regularly practice this behavior, and one of us (SKT) has observed both their frustration and perseverance when it doesn't work out. But failure seems to be a very rare result in adult locomotion. Given the unique set of materials and conditions for each tree sway/gap crossing event, this behavior supports the first three of our cognitive predictions above. Anecdotal observations of tree sway reported in Thorpe et al. (2007) suggest that orangutans can also detect new positive and negative affordances if tree sway supports confound their expectations and exploit these appropriately (P4). For example, when a female orangutan traveling with her adolescent son failed to oscillate a tree trunk to sufficient magnitude to cross a gap, the son moved to a higher bough in the tree. This increased the effective mass of the tree trunk about the point of oscillation, and both were able to cross the gap. The fact that this positional adjustment worked first time suggests they had a fairly nuanced understanding of how to modify the mechanical behavior of the tree trunk.

Although monkeys regularly bounce on branches and occasionally seem to pump horizontal branches up and down before leaping into the next tree, they never seem to do so in a way that allows them to utilize the elastic recoil of the branch. Indeed they often pause after they have pumped the branch for the oscillations to reduce and do not leap at the point of the recoil at which they could benefit from energy return (SKT, pers. obs.).

## Arboreal Cognitive Maps

Foraging for arboreal animals (particularly frugivores or insectivores) is a complex task. Animals must locate food sources that might be widely spread throughout a forest and which are often either ephemeral or intermittently available, so they must also track phenology (Garber and Porter 2014). Furthermore, they must balance efficiency of travel between these resources, energy gain and nutrient balance, while minimizing predation risk and avoiding missing out on ephemeral foraging opportunities away from their route. To make the task more challenging still, the physical structure of the forest often prevents the animal from seeing the goal it is heading for (or any of the landscape features associated with it) from a distance. Thus, the ability to store, recall, and integrate detailed spatial information (e.g., Di Fiore and Suarez 2007; Garber and Porter 2014) and potentially to plan routes efficiently in advance of travel (Janson 2014) is likely to play a critical role in foraging success.

This constraint on visibility is reflected in the way in which researchers conceptualize different scales of navigation in forests: “small-scale” space is defined by the space in which an animal can gain different viewpoints or perspectives of a set of landscape features associated with feeding sites or the feeding sites themselves. In contrast, “large-scale” space is an area in which multiple viewpoints are not possible (Garber and Dolins 2014). The physical size of each area will vary substantially depending on the type of forest environment and the location of the animal within the vertical structure, for example, within or below the canopy. Two main strategies have been proposed for navigating within these spatial scales. Animals may construct a network or route-based (topological) mental map by storing the locations of salient landmarks (the nodes or orientation points), which are linked by familiar and reused routes on which the animals travel (Dolins and Mitchell 2010; Garber and Dolins 2014). Alternatively, animals may use a coordinate-based system, in which they store the coordinates of salient resources directly, providing the flexibility to visit the points in a different sequence and make novel shortcuts between them. A coordinate-

based system has been hypothesized to be possible only in small-scale space (Garber and Dolins 2014), and accordingly among primates, evidence is currently limited to chimpanzees traveling terrestrially within forested landscapes (Normand and Boesch 2009). Since forest canopy blocks many of the visual cues available to help animals navigate using landmarks, it is less clear whether chimpanzees or any other species are able to employ this strategy within this large-scale space. In theory, the use of a coordinate-based system (and to a more restricted extent, a route-based system) would allow animals to plan their routes several steps in advance, optimizing their path between foraging resources, fulfilling prediction **P3**. However, current evidence does not provide support a multi-step planning ability (e.g., Noser and Byrne 2014; Janson 2014), at least in somewhat artificial foraging experiments.

Our understanding of the cognitive maps of animals is confounded however by the fact that in any foraging decision, multiple ecological drivers will be at play, particularly in forest canopy. This is nicely demonstrated by Garber and Porter’s (2014) study that examined the arboreal foraging strategies of wild saddleback tamarins (*Saguinus fuscicollis weddelli*). They present data on daily travel routes, the direction of travel, the relationship between the distance actually traveled and the straight-line distance, and identification of the locations at which they changed direction to revisit feeding sites. They found that saddleback tamarin foraging behavior was most consistent with having a route-based mental map. However, they also showed that by not traveling in a straight line to revisit nearby feeding sites, the tamarins were able to update ecological information on resource availability and distribution. Thus the costs of not taking the most efficient path appear to be offset by the benefits of using multiple spatial strategies and travel patterns to more effectively locate and monitor new feeding sites.

## Caring for Arboreal Animals in Zoos

The cognitive demands of life in the forest canopy have important implications for our ability to

provide for the welfare of arboreal animals in zoos and sanctuaries. Forest is a complex and changeable environment in which large-bodied arboreal species clearly have to constantly think about their environment – how supports will behave under their weight as they move, where to rest, which food resource they should exploit next, and what route they should take to reach feeding and sleep sites. Dealing cognitively and physically with complexity and change is a fundamental aspect of their daily lives and is central to their ability to adapt to variable environments and to cope with adverse conditions. Without doubt this needs to be built into the enclosures of captive arboreal species.

## Conclusion

The study of the cognitive demands of arboreality falls into a broader area of research that investigates what animals understand about the properties of their physical environment and how they deal with complex and dynamic environments. Our results suggest that, as the largest-bodied arboreal species, orangutans meet most of the predictions we made about the cognitive abilities that would be required to thrive in forest canopy. They clearly understand and can reason about the physical behavior and affordances of arboreal supports and the physical effects of their own actions. They can also detect new positive and negative affordances if supports confound their expectations and exploit these appropriately. There is less evidence currently available that they can evaluate routes well in advance of movement or plan arboreal routes using coordinate-based maps. There is much less information available for other arboreal species, which provides scope for lots of exciting research projects to test the extent to which other arboreal animals have evolved advanced cognitive abilities as a consequence of the challenges of life in the forest canopy.

## Archaea

Suman Yadav

Department of Botany, Institute of Science,  
Banaras Hindu University, Varanasi, UP, India

## Definition

Archaeobacteria are group of microorganisms that are anaerobic autotrophs, come under a separate domain, and live under extremely hostile condition.

## Introduction

Archea have inhabited Earth for nearly 4 billion of its 4.6 billion years in existence, making them possibly the oldest living life form (Schopf 1983). Early time the earth is thought to have very less oxygen, but ample carbon dioxide. Earlier the bacteria and archaea did not require oxygen, but utilize carbon dioxide. In two billion years, they have covered the ocean floors, forming strong, collective mats. However, around 2.4 billion years ago global oxygen levels increased that may be due to release of oxygen from the Earth's crust (Rowland 2010). Like eukarya and bacteria the archaea is also diverse in nature both morphologically and physiologically. Morphologically they may be rod shaped, spherical, cuboidal, spiral, plate shaped, and irregular. Some are single celled and some are filamentous or aggregates. Their diameter range is from 0.2 to over 15  $\mu\text{m}$ . Some filament can grow up to 200  $\mu\text{m}$  in length.

They can be either gram positive or negative, but the cell wall is unique in archaea containing ether linkage in lipids while in bacteria the lipids in cell wall have ester linkage. They can multiply by binary, multiple fission or by fragmentation. They are found as anaerobic, aerobic, and as facultative anaerobes. They range from chemolithoautotrophs to organotrophs. They include psychrophiles, mesophiles, and hyperthermophiles that can grow above 100 °C (Willey et al. 2011). Archaea today have a wide variety of unique metabolisms that allow them to live in the most conducive places on Earth. They can eat iron, sulfur, carbon dioxide, hydrogen, ammonia, uranium, and all sorts of toxic compounds, and from their utilization they can produce methane, hydrogen sulfide gas, iron, or sulfur. They have the potential to turn inorganic material into organic matter, like turning metal to meat. This unique potential paved the way for their survival in oxygen-free habitats, boiling sulfuric acid pools near volcanoes, sulfur hot springs, glacial ice, methane seeps, rock four miles into the Earth, desert sands, acid mines, oil leaks, polluted waters, and toxic waste dumps (Rowland 2010). Recently, a species of archaea is reported as the Archeal Richmond Mine acidophilic nanoorganisms (ARMAN) comprising Microarchaeota and Parvarchaeota discovered in 2006 (Baker et al. 2006). With the advancement

in technology in 1990s, for the first time Woese's group sequenced the entire genome of an archaea, *Methanococcus jannaschii*, in 1996. *M. jannaschii* lives in hydrothermal vents on the ocean floor under extremely high pressures and proclaimed as a representative of the third domain (Rowland 2010). Whenever you see a hot, muddy, acidic spring, you are probably seeing the results of a thriving community of archaeal cells called *Sulfolobus*. This is the archaea most often isolated and most well-known by scientists. In sulfuric hydrothermal areas, it oxidizes sulfur into sulfuric acid, which helps to dissolve the rocks into mud (Yellowstone NPS).

### Phylogenetic and Metabolic Diversity of Archaea

Haeckel in 1866 challenged the formally proposed plant animal system classification system and wanted to separate the protists from plant and animal (Haeckel 1866). Later, Copeland further modified and placed bacteria in separate branch and Whittaker created fifth for fungi (Copeland 1938). Later, Carl Woese, by molecular level study, divided the living world into three distinct groups, i.e., Eubacteria, Eukarya, and Archaea (Fig. 1).

**Archaea, Fig. 1** Universal phylogenetic tree in rooted form, showing the three domains (Woese 1994)

Small subunit of ribosomes provides an excellent example as one structural feature in the small subunit of ribosomal RNA by which the eubacteria is distinguished from Archaeobacteria and eukarya (Gupta 1998). Based on the physiological and morphological differences the archaea is divided into five major groups, i.e., methanogenic archaea, archaeal sulfate reducer, extremely halophilic archaea, cell wall-less archaea, and extremely thermophilic sulfate reducer (Table 1). However, based on the phylogenetic evidences, the Bergey's manual has divided the archaea into two major phyla euryarchaeota (Eurus – wide, archiose – primitive) and crenarchaeota (Cren – spring). The euryarchaeota is versatile in their ecological niches and metabolic pattern. Methanogens, extremohalophile, sulfate reducer, many extreme thermophile with sulfur-dependent metabolism come under this phyla. The crearchaeotes resemble to the ancestors of archaea and all the species that belong to this group are thermophile and hyperthermophile.

Based on the 16S rRNA nucleotide sequence, recently a new phyla is gaining acceptance which is named as Korarchaeota (from the Greek word “Young man”). Yet the fourth phyla has also been suggested by the discovery of hyperthermophilic archeon *Nanoarchaeum aquitans* from submarine vent. *N. equitans* live symbiotically with the other genus *Ignococcus* that belong to Crenarchaeota, an autotrophic sulfur-reducing

bacteria. It has not been cultured so its physiology is hard to study. Both genus vary in their size so the cells can be studied for genome analysis. So, there are two accepted phyla of archaea that are reported till date. Later, by the use of advanced techniques and phylogenetic-based study many phyla have been generated, but they are not well accepted. Archaea mainly include the species that carry out the chemolithotropic and chemoorganotrophic metabolisms. They do not have a chlorophyll pigment but a unique form of energy generation occurs in some of the halophilic species.

Energy metabolism process is unique in some archaeal group like methanogens where the methane is produced by anaerobic process where carbon dioxide is the electron acceptor and hydrogen is the donor, or by catabolism of some organic compounds. Chemoorganotrophy and anaerobic fermentation are well studied in certain species of archaea. Halophiles and some thermoacidophiles are found to be aerobic, while anaerobic respiration in which the elemental sulfur is used as an electron acceptor is widespread in *Crenarchaeota*. Autotrophy is largely distributed in archaea. It is concluded that many catabolic pathways in the archaea are found that are very similar to bacteria, a good reminder that metabolism has a long evolutionary history. With this background and the phylogeny of Archaea firmly in mind, we now consider the organismal diversity of this fascinating domain of life.

**Archaea, Table 1** Groups of archaea based on morphological and physiological differences

| Group                                             | General characteristics                                                                                               | Representative genera                                      |
|---------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------|
| Methanogenic archaea                              | Strict anaerobes. Methane is the major metabolic end product                                                          | Methanobacterium<br>Methanococcus<br>Methanomicrobium      |
| Archaeal sulfate reducer                          | Irregular gram negative, autotrophic growth with thiosulfate and H <sub>2</sub> , trace                               | Archeoglobus                                               |
| Extremely halophilic archaea                      | Rods, cocci, or irregular shaped cell, primarily chemoorganoheterotrophs                                              | Halobacterium<br>Halococcus                                |
| Cell wall-less archaea                            | Thermoacidophilic, chemoorganotrophic, facultative anaerobe                                                           | Thermoplasma                                               |
| Extremely thermophilic S <sub>0</sub> metabolizer | Gram negative, filaments or cocci, obligately thermophilic, acidophilic or neutrophilic, autotrophic or heterotrophic | Desulfurococcus<br>Pyrodictium<br>Pyrococcus<br>Sulfobolus |

## Archaeal Cell Wall and Membrane

Archaeal cell ranges from 0.1  $\mu\text{m}$  to over 15  $\mu\text{m}$  diameter, and it occurs in many shapes more commonly as sphere, rod, spiral, and plates (Krieg 2005). Archaea can stain either gram positive and gram negative though they lack muramic acid and D amino acid that make up peptidoglycan (Esko et al. 2009). Some species form aggregates and filament of cells up to 200  $\mu\text{m}$  long. The nature of membrane lipid of the archaea is the distinctive feature. It differs from bacteria and eukarya in two ways. The first one is they contain hydrocarbon derived from isoprene units – five carbon branched molecules. The second is the hydrocarbon that is attached to glycerol by ether links rather than ester links (Fig. 2). When the two hydrocarbon chains are linked by glycerol, they are known as diether. Cells of the archaea can adjust the length by cyclizing the chains to form pentane ring that is more densely packed in the membrane, making them more stable at high temperature. It is also reported that the archaea increase the number of cyclopentane ring as the growth temperature increases. Seventy to 90 percent of the archaeal lipids are polar and remaining are nonpolar and are usually derivatives of squalene. Although there is significant difference in membrane lipids, the basic structure and design of archaea is similar to bacteria and eukarya like there are two hydrophilic surfaces and hydrophobic core. It is expected that from their need for stability, the membranes of extreme thermophiles such as *Thermoplasma* and *Sulfobolus*, that grow

best at temperature over 85  $^{\circ}\text{C}$ , are almost completely tetraether monolayer. Archaea living in moderately hot environments have membrane containing some region with monolayer and some with bilayers. Without the constraints of the conserved molecule peptidoglycan, archaeal cell walls can be quite diverse. For instance, some methanogenic archaea have pseudomurein (a peptidoglycan-like polymer that is cross-linked with L-amino acids), while others contain a complex polysaccharide similar to the chondroitin sulfate of animal connective tissue. Interestingly, some hyperthermophilic archaea and methanogens have protein walls.

## Genetics and Molecular Biology of Archaeobacteria

Many genomic features of archaea are similar to bacteria and eukarya. Generally the genomic size of archaea is smaller than the bacterial genome. *Bacillus subtilis* genome size is 4.20 Mb while *Pyrobaculum aerophilum* genome size is 2.22 Mb and that of *Methanothermobacter thermautotrophicus* is 1.75 Mb. The largest genome size of Archaea is reported in *Methanosarcina acetivorans* with 5,751,492 base pairs (Galagan et al. 2002). Variation in G+C content (from about 21% to 68%) is the sign of archaeal diversity. The complete genome sequenced Archaea is found to have similarity with bacteria and eukarya. About 30% of all genes of archaea encoding proteins involved in transcription,

### Archaea,

**Fig. 2** Phospholipid membrane of archaea, bacteria, and eukarya

translation, or DNA metabolism shared similarity with eukarya. In contrast, a large number of the genes shared only between *bacteria* and *Archaea* are involved in metabolic pathways. In addition, evidence exists for horizontal gene transfer between these two domains, especially between thermophilic bacteria and archaea. Archaea have single circular chromosome and replication is bidirectional like bacteria. However, in sequenced archaea it is reported that the replication origin is flanked by genes encoding the eukaryotic-like initiation protein Cdc6/Orc1 and few archaea have multiple origin. Further, the genome analysis revealed that some of the replication proteins are similar to bacteria and others are unique to those of archaea. Some archaea have still dissimilarity with bacteria in having eukaryotic-like histone protein that binds to DNA and forms nucleosome-like structure. Transcription in archaea is more similar to eukarya than bacteria with Archaeal RNA polymerase being very close to its contemporary in eukaryotes (Allers and Meverch 2005). Archaea have only one type of RNA polymerase and its structure and function is close to that of eukaryotic RNA polymerase II with similar protein assemblies that help in the binding of the RNA polymerase to gene's promoter, but other factors are close to bacterial transcription factor.

## Genetic Exchange and Gene Transfer

Archaea reproduce asexually but DNA transfer and homologous recombination between closely related individuals occur frequently in the populations and have a key role in the formation of archaeal species. Moreover, the horizontal gene transfer (HGT) between the distantly related species can transfer novel functions and features and ignore the need for de novo evolution in the recipient (Cadillo-Quiroz et al. 2012). Recently 134 archaeal genomes are analyzed and it was found that many contained signatures of horizontally transferred DNA from bacteria, especially the methanogens, and the majority of the transferred genes were presumed to be functional (Nelson-Sathi et al. 2015). Chromosomal and

plasmid DNA exchange in halophilic archaea occurs by cell fusion-based manner (Naor et al. 2012). Moreover, a recent study reported the first archaea-specific DNA transport system seems to have a crucial role, especially under conditions of DNA damage (Van Volferen et al. 2016). The genes that are transferred horizontally in archaea mostly originate from bacteria, while the remaining genes are transferred from archaea or in some cases from eukaryotes (Brochier-Armanet et al. 2011). High rates of interdomain horizontal gene transfer is revealed by phylogenetic analysis in Marine Thaumarchaeota and Euryarchaeota that acquired 24% and 30% of their genes from bacteria, respectively (Brochier-Armanet et al. 2011).

## Thermostability in Archaea

The archaea have a special feature that helps to tolerate a very high temperature and now it is a burning issue for research. At high temperature, the protein of mesophilic microorganism got denatured by changing the state into unfolded form. In thermophilic archaea, these proteins remain normal and work properly. There are some structural strategy used by thermophiles that include increased hydrophobicity of protein core, an elevated number of ionic interactions on the protein surface, increased atomic packing density, additional hydrogen bonds, and shorter surface loop structures. It is found that the thermostable proteins have relatively higher number of valine, glutamate, lysine, and a fewer glutamine and valine residues. In addition to this, the thermophiles also have some chaperones that assist in refolding of the partially denatured proteins. They have a reverse DNA gyrase that induces positive rather than negative supercoils into DNA. Positive supercoiling increases the DNA thermostability (Presscott) (Willey et al. 2011).

## Phylum Crenarchaeota

This phylum has one class *Thermoprotei* divided into four orders and six families. Order

**Archaea, Table 2** Comparison between archaea and other domains (Willey)

| Features                       | Prokaryotes                                                              | Archaeobacteria                                | Eukaryotes                                         |
|--------------------------------|--------------------------------------------------------------------------|------------------------------------------------|----------------------------------------------------|
| <b>Genomic structure</b>       | Circular chromosome                                                      | Circular chromosome                            | Multiple linear chromosome                         |
| <b>Cell membrane</b>           | Ester linked lipid<br>Peptidoglycan                                      | Ether linked lipid<br>Pseudopeptidoglycan      | Ester linked lipid                                 |
| <b>Internal cell structure</b> | No membrane bound organelle                                              | No membrane bound organelle                    | Membrane bound organelle                           |
| <b>Metabolism</b>              | Phototrophy, autotrophy, aerobic and anaerobic respiration, fermentation | Methanogenesis is unique in archaea            | Photosynthesis, cellular respiration, fermentation |
| <b>Reproduction</b>            | Asexual reproduction, horizontal gene transfer                           | Asexual reproduction, horizontal gene transfer | Asexual and sexual reproduction                    |

*Thermoproteales* contains gram negative anaerobic to facultative and, hyperthermophilic rod shaped. Order *Sulfolobales* are coccus shaped thermoacidophiles and *Desulfurococcales* are coccoid or disk-shaped hyperthermophiles. *Caldisphaerales* are thermoacidophilic, aerobic, heterotrophic cocci. Many of these thermophiles are sulfur dependent. It may be used as either an electron acceptor in anaerobic respiration or an electron donor by lithotrops. They live in the place of geothermally heated soil or water that has abundant elemental sulfur.

**Phylum Euryarchaeota**

It is very diverse phylum with many genera methanogen. Five major physiologic groups within the euryarchaeotes are methanogens – They are considered as strict anaerobe and get the energy by converting CO<sub>2</sub>, H<sub>2</sub>, formate, methanol, and acetate into methane or methane and CO<sub>2</sub>. They are the largest group of cultured archaea. Halobacteria – They are other euryarchaeal groups which are aerobic chemoorganotrophs with respiratory metabolism. Extreme halophiles demonstrate a wide variety of nutritional capabilities. Thermoplasma – They are thermoacidophiles that lack cell walls. They grow in refuse piles of coal mines. They contain large amount of iron pyrites that is oxidized to sulfuric acid by chemolithotrophic bacteria. Extremely thermophilic sulfur reducer – This group have the class Thermococci with one order Thermococcales. They are strictly anaerobic

and can reduce sulfur to sulfide. Sulfate-reducing euryarchaeota – They are represented by the class Archaeoglobi. It can extract the electron from hydrogen, lactate, and glucose, and reduce sulfate, sulfite, or thiosulfate to sulfide. It is extremely thermophilic and is isolated from marine hydrothermal vents (Table 2).

**Conclusion**

Archaea can be aerobic, anaerobic, and facultative anaerobe occurring in extreme conditions and phylogenetically more close to eukarya than bacteria. It is multiplied by binary, multiple, or fragmentation. They can survive in extreme situation so they have the enzyme system that are utilized for further industrial application and molecular level study of organisms.

## Intellectual Biography

Aristotle was born in Stagira, Chalcidice, in 384 BCE to Phaestis of Chalcis and Nicomachus,

a physician at the court of King Amyntas II of Macedonia. While it is likely that Nicomachus died when Aristotle was young and Proxenus, a citizen of Atarneus, raised him. Aristotle's medical legacy may have spurred his enthusiasm for biology. His focus on systematic research, dissection, and the sheer size of the biological writings in the corpus are indications of early medical training. At the age of 17, Aristotle entered Plato's Academy and remained a scholar there until the death of Plato around 347 BCE. In his later ethical writings, Aristotle delineates the highest type of friendship from that of pleasure and utility. Plato's Academy was a community of just this kind of friendship: one grounded in a life of contemplation and virtue, a life that can only be sought in the development of the intellect and the pursuit of the good in political life. Legend has it that Plato remarked that his school consisted of two parts: the body of students and "The Mind" of Aristotle, the first of Aristotle's nicknames (Edel 1982). Plato also called him "The Foal" meaning that Aristotle kicked his teachers the way a foal kicks its dam (Natali 2013). His peers named him "The Reader," a jibe referring to the servant who read aloud to the students, the common way of engaging texts in ancient times (Edel 1982). Aristotle did his *own* reading and would famously read so late into the evening that he held a rock over a tin pan to wake him if he dozed off (Edel 1982; Natali 2013).

At the Academy, Aristotle's education included dialectical discussions and scientific activity including research into astronomy and the natural sciences. We can imagine, and have some evidence for, members of the Academy rigorously debating Plato's theory of the forms: the ontological notion that reality is distinguished by what is material (ephemeral, corporeal, particular objects) and what is formal (eternal, incorporeal, universal objects). Material objects are perceived with the senses but strict knowledge of them is not possible. For Plato, scientific understanding (strict knowledge) amounts to logical demonstration, that is, deduction from what is necessary. Knowledge consists of a set of universal, necessary, eternal, and true propositions. As

such, knowledge corresponds to that segment of reality that is eternal and universal. These "ideas" (*ideas*—another term Plato uses for the forms—*eidos*) are the objects of knowledge and, because knowledge is of what is real for Plato, constitute reality. Material objects constitute a secondary level of reality at best or are mere illusion at worst. This ontological and epistemological theory must have been at odds with the empirical predilections of a member of the cult of Asclepius because Aristotle famously argues that understanding begins with sensual *perception* in his *Posterior Analytics*. The basis of human knowledge is the ability to retain and revive these assorted sensory percepts, what he calls *memory*, and from *experience* humans notice symmetry (regularity) and asymmetry between and among properties. Experience is the basis of *intuition*, which is the first step in logical *demonstration*, the form that scientific propositions take according to Aristotle. In other words, it is through the experience of what humans perceive, i.e., particular objects, that they can ultimately gain understanding of what is eternal, universal, and necessary, i.e., the form. Aristotle's theory of knowledge is grounded in his theory of reality wherein the form's existence is dependent upon and concomitant to the matter's existence. The empirical basis for his epistemology and his argument, contra Plato, that form is embedded in matter are why he is commonly referred to as a naturalist and considered to have developed a new school of thought.

However, we interpret Aristotle's theories in relation to those of Plato, there is little doubt that Aristotle revered his master. He studied with Plato for nearly 20 years and famously elegized him as:

...the man whom it is not lawful for bad men even  
to praise,  
Who alone or first of mortals clearly revealed,  
By his own life and by the methods of his words,  
That a man becomes good and happy at the  
same time.  
Now no one can ever attain to these things  
again. (Jaeger 1934, p.107)

Plato's nephew, Spseusippus, succeeded him as head of the Academy. Some scholars intimate professional jealousy and Aristotle's biological

emphasis in philosophy, as opposed to that of Speusippus who leaned toward the mathematical, as the reasons for his departure from Athens. However, some regard his departure not as secession but an attempt to spread the political philosophy of the Academy. Aristotle and Xenocrates were invited by Hermias, then ruler of Assos, possibly to serve as political advisors but there is also evidence that there was a branch of the Academy there welcomed by Hermias. What appears clear is that anti-Macedonian sentiment fueled by the great Athenian orator Demosthenes influenced Aristotle's emigration. At Assos, Aristotle met and married a young woman named Pythia, who was Hermias' niece or perhaps his daughter, and they had two children, Pythia and Nicomachus. Aristotle's famous work on ethics, the *Nicomachean Ethics*, was named after their son and they also raised Proxenus' son, Nicanor, who became a general under Alexander. Much of Aristotle's research on the life of animals appears to have been done between 347–335 BCE at Assos, Atarneus, Lesbos, and Macedonia because the particular species he observes are indigenous to these regions and he consistently mentions places especially in and around Mitylene, Lesbos, in the biological writings (Natali 2013). Aristotle took his bride to Lesbos in 345 BCE. There he met his closest collaborator and eventual heir to his school, Tyrtamos of Eresos, whom Aristotle would rename Theophrastus, which means "divine speech." While Aristotle would establish in his *Historia animalium* (*Inquiry into Animals*) the founding document of biology, Theophrastus would do the same for botany in his *Historia plantarum* (*Inquiry into Plants*) (Fortenbaugh and Sharples 1988).

In 343–342 BCE, Aristotle accepted the invitation of Philip of Macedon to tutor his son Alexander. While there is much conjecture about the content of Alexander's education, some scholars suggest that Aristotle's relationship to the future leader of the known world proved beneficial to his own scholarship. Aristotle returned to Athens in 335 BCE to establish his own school at a grove sacred to the god Apollo Lyceus. At the Lyceum, Aristotle would discuss

with his students and write about a number of exotic species that scholars argue were actually observed in detail by his nephew, Callisthenes, who accompanied Alexander and wrote of his eastward conquests. Aristotle focused on the systematic collection of research material and established the first library at the Lyceum. He was also the first thinker to devise a system of logic. His greatest contribution to the field was the syllogism but he may also be credited with numerous metalogical theses such as the principle of excluded middle, and the laws of bivalence and non-contradiction. Aristotle "walked about" with his students in the morning discussing philosophy, earning them the name "Peripatetic." He carried on his work at the Lyceum organizing and writing most of the corpus until the death of Alexander in 323 BCE. Athens revolted, anti-Macedonian sentiment rose yet again, and Aristotle was charged with impiety in part for the hymn he had written for Hermias praising him as a god (Natali 2013). Aristotle decided not to face trial and retreated to Chalcis. He explains in a letter to Antipater, Macedonian general, and executor of Aristotle's will, that he would not let Athens sin twice against philosophy referring to the trial of Socrates. Antipater crushed the Athenian revolt and Demosthenes drank poison in order to avoid capture. Aristotle passed a year later from a stomach ailment. He had created the first major library, invented logic and biology, tutored the greatest ruler of the ancient world, and would influence the thought of several cultures for millennia to come.

## Scientific Method and Observation

Aristotle is the first major thinker to dedicate a special branch of knowledge to the systematic study of animal life. Of all the sciences he considers, he writes the most about biology. His research on animals constitutes roughly 25% of the extant corpus. *Inquiry into Animals*, *Parts of Animals*, *Generation of Animals*, *On the Psyche* (*De Anima*), *Movement of Animals*, *Progression of Animals*, *Parva naturalia* (a number of short essays on natural functions), and the last book of

the *Meteorology*, all contain discussions of animal life. Aristotle's method begins with (a) an inquiry grasping the differences between and the attributes of various animals and proceeds with an (b) investigation into their causes. The method of investigating the reasons why certain animals have particular attributes (b) Aristotle spells out in some detail at the opening of his *Parts of Animals*. Why it is that the elephant has an elongated trunk or the dolphin snores is the result of natural processes that are not random for Aristotle. Animals develop in specific ways in order to perform the functions that constitute their particular ways of living. They are unities of matter and form and he considers the ability to sufficiently explain the natural processes that result in animals developing in the ways they do the primary role of the natural philosopher.

In his various works concerning animal life, Aristotle presents descriptions of the attributes of over 200 different species. The *Inquiry into Animals* especially centers on these varied attributes and provides the first systematic classification of animals. Modern biological taxonomy is credited to Carolus Linnaeus' publication of the tenth edition of *Systema naturae* in 1758 with its tidy, hierarchical categorization of class, order, genus, and species (Leroi 2014). Many of Aristotle's kinds (*genê*) and greatest kinds (*megista gene*) correspond to modern classes, orders, genus, and species, but his classification lacks the range and coherence of modern taxonomy (Lennox 2001). This is due to his aim: Aristotle seeks to discover the nature of living things. For him, this amounts to demonstrating how it is that the attributes of an animal serve its purpose as a living being. His ordering of animal life is, therefore, teleological. It takes into account the genesis of animals, the material that serves as the locus for their development, the form or structural organization of their developing matter, and the purpose or final end of their development. Aristotle's *Generation of Animals* provides an explanation for the causal relation between form and matter in the early development of animals reflective of his patriarchal culture. He argues throughout that the female is the material cause of generation because she provides the passive

matter out of which the embryo is formed. The male, on the other hand, is the efficient cause of generation because his semen provides both the form of the embryo and the catalyst for its development (Connel 2016; Cooper 1988; Mayhew 2004).

The obvious problems with this and some of this other theories may, in part, be attributed to the way in which he gathered information. His method of acquiring data, what he calls examination of "*phainomena*," involves direct observation in some instances. However, there were many exotic species that Aristotle did not directly examine but were meticulously described to him (see Callisthenes' contribution above), and he considers analysis of informed and sometimes uninformed opinions (*doxa*) of animal anatomy and behavior as grist for the mill (Leroi 2014). These opinions could be those of other great thinkers including mythmakers and natural philosophers, people living adjacent to specific fauna, hunters, fishermen, etc. They sometimes led Aristotle to err; for instance, he infamously contends that the bison can defend itself from assailants by repeatedly projecting its excrement over long distances, excrement so pungent that it can burn the fur off hunting dogs and is only of this nature when the animal is alarmed (630a19–630b18). He also believes that spontaneous generation occurs in some animals, such as testaceans, anemones, grey mullets, and eels because he finds no evidence of their reproduction. But some fishermen's tales also led him to keen observations; Aristotle collectively names dogfish, rays, torpedo fish, and sharks *selakhe*, noting their cartilage where most fish have bone, but he specifically notes the unique reproductive structures of the smooth dogfish, *Mustelus mustelus*. Smooth dogfish are born live and are connected to their mother's uterus by an umbilical cord and placenta, features thought exclusive to mammals. Pierre Belon and Guillaume Rondelet confirm Aristotle's findings in the sixteenth century and Johannes Muller discovered it again in 1839 in his *Über den glatten Hai des Aristoteles* (*On Aristotle's Smooth Shark*) (Leroi 2014). Further, Aristotle comments that a tentacle of certain male octopi (*Argonauta argo*) is involved in

coitus. This tentacle was thought to be a parasite, because it commonly broke off and was discovered inside the female, until the mid-nineteenth century when it was confirmed a penis-tentacle.

One of Aristotle's most famous fish tales involves the paternal instincts of the Macedonian catfish. His description of the catfish's breeding habits is precise, including external fertilization, the resulting egg envelope, the development of embryonic eyes, and the slow growth of the larvae. But the observations he makes of the male protecting the young are particularly keen:

Of river-fish, the male of the catfish is remarkably attentive to the young. The female after parturition goes away; the male stays and keeps on guard where the spawn is most abundant, contenting himself with keeping off all other little fishes that might steal the spawn, and this he does for 40 or 50 days, until the young are sufficiently grown to make away from the other fishes for themselves. The fishermen can tell where he is on guard; for, in warding off the little fishes, he makes a rush in the water and gives utterance to a kind of muttering noise. He is so earnest in the performance of his parental duties that the fishermen at times, if the eggs be attached to the roots of water-plants deep in the water, drag them into as shallow a place as possible; the male fish will still keep by the eggs, and, if it is young, will be caught by the hook when snapping at the little fish that come by; it, however, he be sensible by experience of the danger of the hook, he will still keep by his charge, and with his extremely strong teeth will bite the hook in pieces. (621a20-b1)

Failing to recognize this extravagant paternal behavior in other European catfish, Louis Agassiz doubted Aristotle's account until he received some Macedonian fish from the physician to the Greek king confirming Aristotle's detailed observations. His assistant Samuel Garman named this novel species *Silurus aristotelis* in 1890, noting the four barbels on its chin in contrast to the six barbels of *Silurus glanis* (Leroi 2014).

## Animal Intellect and Teleology

Aristotle characterizes deer as possessing preeminent practical intelligence (*phronêsis*) in comparison to other quadrupeds. This is because of their effectiveness at avoiding threats in their environment. For example, stags when fattening up in the

fall shun their usual haunts in order to evade detection by predators. They also hide when shedding their antlers so that their vulnerability is inconspicuous. A doe will give birth at roadsides in the hope that human traffic will scare off predators. She will then swallow the afterbirth and lead the faun to a lair of precipitous rock with only one entrance in order to better protect her offspring. Aristotle thinks other animals display intelligence in safeguarding too. He cites cranes setting lookouts for protection while sleeping. He believes deer, dogs, goats, panthers, and tortoises use medications to counteract poisons and alleviate pain (Foster 1997). He contends that all animals perceive weather changes and, according to their natures, either migrate before the frost bites or make other provisions. Finally, he notes birds and insects exhibiting technical proficiency (*technê*) in constructing nests and other protective environs.

All of this amounts to the possibility that animals possess intellect (*vous*) or reason (*logos*), a possibility that, oddly enough, Aristotle denies. What Aristotle does grant animals is sense perception and the cognitive ability to mentally represent percepts (a process he refers to as *phantasia*). Humans can *willingly* recollect these percepts and, in the process, stimulate the desire to pursue or avoid the objects represented. They can further signify these percepts linguistically and consider whether their pursuit or avoidance is conducive to their long-term good. These capacities (intentional memory, language formation, and consideration of future welfare) Aristotle considers unique to humans. However, he also believes nature proceeds according to a rational design because it is teleological. Thus plants and animals may not possess reason but their behavior can be exhibitively of reason. Plants seek out nutrition and grow but do not do so consciously. Animals seek nourishment and do so with the aid of sensation and appetite. They perceive what is painful as harmful and what is pleasurable as beneficial aiding in their ability to survive. They can recall past sense impressions in order to aid in this process, but they cannot do so willingly. Consideration of future welfare appears difficult, if not impossible, according to this

schema. But Aristotle's extraordinary examples of animals' capacities to protect and ward off future harms are for him exhibitiv of the rationality of the cosmos rather than that of individual beings.

## Definition

A heightened physiological response or behavior to a stimulus (e.g., sweaty palms, increased heart rate, focused attention).

## Introduction

Arousal is a state that keeps us attentive or in some instances, makes us aware of our surroundings. For example, biologically, arousal can help us survive because we become aware and attentive to the current environment. Studies have found

arousal is part of the adrenergic system, with Pribram and McGuinness (1975) defining arousal as a physiological response to input, centered in the amygdala (see also Sharot and Phelps 2004; Styliadis et al. 2018). Arousal is a key component to survival in nature because it can cue the flight-or-flight system protecting us when we might be at risk. Arousal brings attention to what is going on around us, so studies might refer to arousal as a level of activation. Pribram and McGuinness (1975) discuss how activation can result in heightened defense responses. We see this when our heart starts beating a bit faster, and we begin to plan how we will approach the situation. This mechanism can be observed across the animal kingdom, for example, when animals hunt for food or sense they are about to be attacked. In humans, arousal can help us learn, memorize, and recall. Arousal can also play a role in our decision-making (Sanbonmatsu and Kardes 1988). We also see arousal as part of emotion processing, particularly the calm-exciting dimension of processing emotional stimuli. However, it is possible *too much* arousal can impair memory when we experience or process traumatic or obscene memories, which can be emotionally charged (Bradley et al. 1992). For these varied reasons, it is important to further research the mechanisms and effects surrounding arousal.

## Measuring Arousal

Since arousal is a heightened state, our bodies have physiological responses to the heightened state (e.g., increased heart rate, sweaty palms). Researchers have used physiological measurements to measure arousal during their studies. One physiological response researchers use to measure arousal is galvanic skin response (GSR) or skin conductance response (SCR). These measurements use the conductivity of human skin to measure changes in the sympathetic nervous system (Shi et al. 2007). Arousal can influence the flight-or-flight system, which is part of the sympathetic nervous system. Once the flight-or-flight system is activated, biological responses like sweaty palms occur, which are often observed in arousal studies. Similarly, pupil dilations, head

movement, pricking of the ears, respiration, and blood flow can be signs of arousal (Pribram and McGuinness 1975). In another example, Libkuman et al. (1999) used exercise tasks to measure physiological arousal by having participants ride on bikes at certain paces. Arousal can also be measured neurologically using machines like magnetoencephalography (MEG) or functional magnetic resonance imaging (fMRI). Another neurological measurement commonly used in arousal studies are event-related potentials (ERPs).

While physiological and neurological responses might be considered objective measurements, researchers must also consider the validity of the materials they use to induce arousal. For example, psychological studies might use pictures, events, and other materials to ensure participants are in an aroused state. Pilot studies are often used to ensure these materials induce arousal in participants during their experiments, or researchers might rely on previous research to locate materials that will induce arousal. For example, Vogt et al. (2008) used emotional pictures from the International Affective Picture System, and these pictures relate to varying arousal states (none, low, moderate, and high) (see also Mather et al. 2009). These pictures were previously piloted to show they can induce different arousal states. Words varying in arousal are also commonly used when studies want to research and measure arousal. Similar to researchers' use of pictures varying in arousal (e.g., high arousal, low arousal), words are selected from previous studies or published normative data testing these words.

Finally, self-report measures are also used to measure arousal, though they introduce more subjectivity to the dataset. One scale used to measure self-report is the Affect Grid. Russell et al. (1989) describe this scale as a grid-type scale where participants place a single mark on a grid according to how they feel. Pleasure-displeasure is placed on the horizontal dimension, while arousal-sleepiness is placed on the vertical dimension. This scale was later tested for validity by Killgore (1998). Another scale used to measure self-report is the How I Feel scale, which is typically used for children ages 8–12 (Walden et al.

2003). For the How I Feel scale, there are 30 statements (e.g., *I was mad very often*) and participants are asked to rate these statements on a scale of one to five, one being not at all true of me and five being very true of me. Of course, self-report is a more subjective measurement than an objective measurement. The more objective measures of arousal – those pertaining to physiological and neurological measures – are likely more valid and reliable than subjective, self-report measures, though the latter do have advantages with easier to collect data.

## Main Findings

Arousal is a well-researched concept among psychologists. An early study by Kleinsmith and Kaplan (1963) examined a hypothesis of preservative consolidation, predicting a pattern perceived under high arousal should show stronger memory and weaker immediate memory. To examine arousal, the researchers measured skin resistance while participants learned paired-associates. These paired-associates were composed of word-number pairs (i.e., three-kiss eight-love). Their results showed low arousal words were remembered more than high arousal words when immediate recall was required. However, in delayed recall, high arousal words were remembered more often than low arousal words, which they classified as a reminiscence effect (i.e., high permanent memory).

In a more recent study, Sharot and Phelps (2004) found similar results. For their study, they examined recognition for neutral and arousing words at two points in time (immediate and 1 day later). Their three experiments showed arousal can facilitate slower forgetting, like Kleinsmith and Kaplan (1963) had found. Sharot and Phelps (2004) found during delayed recall, arousing words were remembered more often than non-arousing words. Their results also showed poorer recognition of neutral words over time, whereas memory for arousing words remained the same or showed improvement over time. Similar findings with animal subjects have been noted (e.g., Cahill and Alkire 2003; Cahill et al. 2003).

These studies show arousal promotes a kind of buffering, in that arousing information (e.g., pictures, events) is preserved over time.

Researchers have also examined arousal as it pertains to encoding. In one example, Bradley et al. (1992) examined memory retrieval after participants rated slides according to their actual emotional reaction (pleasantness or unpleasantness). Arousal, valence, and dominance were rated after each slide using the Self-Assessment Manikin (SAM; Bradley and Lang 1994) rating system. Participants were divided into immediate recall and delayed recall conditions. In immediate recall, slides rated as pleasant promoted higher arousal, which resulted in better recall. However, the delayed recall condition performed in a different way. The slides rated as unpleasant were recalled more often than pleasant slides, and the unpleasant slides brought higher arousal. Their results suggested high arousal assists with memory performance, when memory for the event's occurrence is probed (Bradley et al. 1992).

Some researchers have noted particular differences between physiological arousal (i.e., running, biking) and emotional arousal (i.e., watching an emotionally charged movie). In a study by Libkuman et al. (1999), the researchers examined the influence of physiological and emotional arousal on recognition memory of central, background, and peripheral parts of an event. Libkuman et al. (1999) found physiological arousal had little impact on memory while emotional arousal helped improve memory for both central and background information. Their results supported previous findings of arousal being an important determinant of an event's memorability (Christianson 1992). Mather et al. (2006) also examined detailed aspects of memory. They were interested in examining how the emotional content of pictures affects participants' ability to remember where it appeared, while also assessing their brain activity while performing the memory tasks. They found poorer short-term memory for the location of highly arousing pictures than lower arousing pictures. In the fMRI results, they found emotionally arousing pictures recruited more attention, which was observed in activation in visual processing areas. Their results supported

previous findings that arousing pictures generate greater attention than neutral pictures. Our attention is interrupted by arousing information as Libkuman et al. (1999) and Mather et al. (2006) found. Similar results were reported by Kleinsmith and Kaplan (1963) and Sharot and Phelps (2004), who showed reduced immediate memory for arousing stimuli (and the reverse effect for long-term memory).

When arousing stimuli catch our attention, researchers have found it can be difficult for participants to disengage from them. Vogt et al. (2008) found these results during their study, where they examined valence and arousal of emotional stimuli, along with their influences on the allocation of spatial attention. Their results showed delayed disengagement of attention from highly arousing pictures, independent of their valence (i.e., across both positive and negative pictures). Additionally, emotionally arousing stimuli can pull attention from other sources. Mather and Sutherland (2011) hypothesize our attention is immediately focused toward emotionally arousing stimuli. They describe emotional arousal as having a “winner-takes-more” effect, in that, when processing information, arousal influences the competition between different stimuli. One important application of their work is the *weapons focus effect*, in which high arousal images – in both laboratory and real-world settings – capture and main attention to such a degree that other information from the environment goes largely ignored (Loftus et al. 1987). One additional application lies in working with trauma and other domains of clinical psychology; research shows mental illness (e.g., depression, PTSD) impairs an individual’s ability to disengage from negative stimuli (e.g., Levens and Gotlib 2010; Vythilingam et al. 2007). Difficulties disengaging from negative stimuli might be due to hyper-responsiveness to threat-related/negative stimuli (Vythilingam et al. 2007). Additionally, disengaging from negative stimuli might be difficult for these individuals because of an insensitivity to positive stimuli (Levens and Gotlib 2010).

These effects can also be observed with non-clinical samples. Delaney-Busch et al. (2016) examined valence and arousal influences on

different states of emotional word processing. They found when emotion is not relevant to the task the participants are performing, the arousal property of emotional words captures attention and brings sustained evaluative processing. An implication of these studies is in eyewitness testimonies. Brown (2003) examined how arousal influences eyewitness memory of an event and how it interacts with contextual reinstatement: a method used to have witnesses recreate a past event. To test their hypothesis, participants viewed slides of different contexts that contained one person or object in the center of the slide. Arousal was measured by asking participants to self-report their arousal for the specific slide. Their results supported context reinstatement procedures enhance recognition memory for non-arousing and unusual events but not arousing events. The results supported previous research showing peripheral information is not remembered as well in an arousing event (Christianson and Loftus 1991). This experiment also replicated enhanced memory for central information in arousing events. The arousal manipulation increased recognition rates for the central position, while decreasing false alarms. Their results supported that narrowing of attention during arousing events affects encoding for other peripheral or contextual information. These results are important to consider because when we find ourselves in an arousing situation, it can be challenging to later recall what happened.

While arousal is often described in terms of its beneficial properties, researchers have found arousal can also present limitations to attention and memory. For example, some have found high arousal can impair memory (e.g., Brown 2003; Mather et al. 2009; Mather et al. 2006; Mather and Sutherland 2011). Since arousal is typically focused on central information, the background and peripheral information can be missed and not encoded for memory. Mather et al. (2009) examined how arousal can limit memory on nearby information. Their results showed arousing pictures impaired memory for background information – a kind of perceptual suppression – though it did not impair memory for any foreground information (see also Brown

2003). Similar to the overstimulation of information during an arousing situation, arousal can have effects on our decision-making. Sanbonmatsu and Kardes (1988) found participants' decision-making was impaired when they were highly aroused, measured in their reduced processing. These results show how arousal pulls cognitive resources to such a degree, that the minimal, remaining resources cannot engage or complete other tasks.

## Conclusion

Arousal has been defined as a heightened state with physiological and behavioral responses to stimuli in our environment. Arousal has been linked to the amygdala, which is part of our sympathetic nervous system. This system plays a part in flight-or-fight responses when we sense danger. Arousal is similarly helpful in maintaining focus and helping us prepare an appropriate response. This focus can also extend to learning, memorizing, and recalling, as arousing stimuli tend to focus our attention (while also limiting our ability to attend to other, background, and peripheral stimuli).

On the other hand, as arousal exists on a continuum, one must also consider the adverse effects of high levels of arousal. Bradley et al. (1992) note too much arousal can impair memory when we experience or process traumatic or obscene memories. This is also important to consider when evaluating an eyewitness's recall. Additional limitations pertain to decision-making and other aspects of complex cognition, in which attention and focus are greatly needed. When we are highly aroused, we can only minimally process additional information, which can impair other tasks. Mather et al. note a need to explore exactly how arousal limits our attention. Individual differences should also be explored, as well as how they interact with participants' mood while processing emotional stimuli. Finally, we ought to delve deeper into the clinical applications of these findings, particularly how these findings relate to trauma. Together, future research can help gain more knowledge on how arousal functions – in

both helpful, survival contexts and those impairing other functioning.

## Definition

The perceiving, learning, and utilizing of information exhibited in the invertebrate animal phylum, Arthropoda.

## Introduction

Arthropods are a widely studied animal group, inspiring interest across a broad range of scientific disciplines due to the diversity of the environments they inhabit and their broad range of ecology. This group’s versatility has resulted in arthropods being the most successful animal group on the planet, with their membership including spiders, insects,

and crustaceans. Arthropods are characterized as a group by their segmented bodies, appendages with joints, a hard external exoskeleton, and a lack of internal bone structures. To the layman, the behaviors of these “lower order” organisms might appear as inflexible or hardwired and reflect the appearance of only limited cognitive abilities when compared to the cognition of vertebrates. However, there exists a wealth of scientific evidence that paints a picture of arthropods as organisms that exhibit large flexible behavioral repertoires, including the ability to perform complex cognitive functions despite their small brain size and limited neuron numbers. The cognitive processes exhibited by arthropods can be as simple as associative learning between a stimulus and a food reward or as complex as navigation using memorized visual cues or the sophisticated communication of the honeybee dance. Within this chapter, we discuss four broad topics concerning the cognitive abilities of arthropods: associative learning, spatial cognition, social cognition, and, finally, distributed cognition. Such an overview is not meant to be exhaustive but rather present an impression of the diverse range of cognitive abilities exhibited by the group.

## Associative Learning

Arthropods show a surprising capacity for learning a wide range of sensory cues that may predict either reward or punishment. These learned cues can be stored over the short or long term for further use. A large portion of the research exploring the learning and memory capabilities of arthropods has focused on associative learning, a cognitive process in which an organism learns through experience to associate certain behaviors with stimuli. This type of learning includes both classical conditioning and operant conditioning and has been widely used in arthropod research to showcase an array of cognitive skills.

## Classical Conditioning

Classical conditioning is a learning process in which an organism learns to associate a biologically neutral stimulus with a potent, biologically

relevant stimulus leading to a behavioral response when the neutral stimulus is presented alone. In the classic learning experiments conducted by Ivan Petrovich Pavlov, dogs learned to associate previously neutral sounds such as the ticking sound of a metronome with the presentation of food. Dogs originally only salivated when the food is present, but over a number of pairings, individuals would begin to salivate at the ticking sound even in the absence of food.

Insects are commonly used subjects in classical conditioning research. For instance, during olfactory learning experiments in honeybees, a restrained bee is presented with a neutral odor, the conditioned stimulus. As this odor is presented to the bee, the unconditioned stimulus, here a small amount of sucrose solution delivered to the bee’s antennae, is also presented. The bee’s unconditioned response to the sucrose is to extend its proboscis, a long tubular portion of the bee’s mouth, which it uses to feed (Fig. 1). After multiple exposures to the odor, followed by the sucrose solution, the bee will begin exhibiting a conditioned response to the odor alone, extending its proboscis when only the odor is presented. Olfactory memories in honeybees can be retained over long time periods when the subject is exposed to repeated presentations, whereas conditioning after only a single pairing will decay over the next 24-h period. Repeated pairings of the odor and sucrose can produce memories of the association that can last over 7 days (Menzel 1999; Giurfa and Sandoz 2012).

Evidence of this associative learning using both olfactory and visual stimuli is present across the arthropod phylum. The Pavlovian salivation response can be replicated by olfactory pairing in cockroaches (Watanabe and Mizunami 2007). Cockroaches were presented with a neutral odor and then a small amount of a sucrose solution. Just as in dogs, the unconditioned response measured was the saliva production in the cockroach’s mouth. After training, conditioned cockroaches increased salivation when presented with the conditioned odor alone but not when presented neutral odor types.

Associative learning can also encompass associations beyond those revolving around attaining food rewards. In a form of classical conditioning

**Arthropod Cognition,**

**Fig. 1** Images of proboscis extension response testing in restrained honeybees.

Individual bees are immobilized inside of metal restraining tubes where only the head, mouth (proboscis), and antennae are free. During classical conditioning testing, the bee is presented a conditioned stimuli (typically a neutral odor) and then a small amount of sugar water (unconditioned stimulus) is delivered to the antennae and proboscis via a small spoon. After multiple pairings of these stimuli, the bee will extend its proboscis when the odor is presented alone. (Image printed with permission from Dr. Randolph Menzel)

A

called aversive conditioning, the unconditioned stimulus presented to the animal is negative, such as an electric shock. After pairing the shock with a previously neutral stimulus, subjects will respond by avoiding this neutral stimulus in future tests. *Drosophila* fruit flies have been shown to readily learn these associations between different odors and electric shock, actively avoiding odors that have been previously paired with the aversive stimulus (Tully and Quinn 1985; Busto et al. 2010). Beyond insects, spiders and crabs show similar cognitive abilities, quickly learning associations between stimuli and visual cues. Hermit crabs are more likely to abandon a home shell for a new shell after experiencing an electric shock within the original. These crabs will also spend less time inspecting a new shell before deciding to swap (Elwood and Appel 2009).

Associative learning can be a strong driver of behavior, to the point where it can lead animals to override instinctive behavior. Certain crab species have an instinctive preference for darker environments due to predation pressures. This preference can be extinguished when bright light is paired

with food rewards. Instinctive behaviors can also be paired with adverse stimuli to decrease their prevalence. Crabs can also learn to avoid dark habitats when these dark environments are paired with aversive stimuli such as electrical shocks. Crabs and crayfish will learn this association and exhibit increased avoidance behaviors such as running responses or fleeing out of the area when darkened habitats are linked with electrical shock (Barr et al. 2008; Magee and Elwood 2013).

**Operant Conditioning**

Operant conditioning is a learning process that involves the frequency of a behavior being controlled by the behavior's outcome. Unlike classical conditioning, during operant conditioning, behaviors are not elicited by a stimulus but instead are shaped by the behavior's subsequent result, which can either be a reward or a punishment. Arthropods are adept at associative learning paradigms. This has made member species, the honeybee and *Drosophila* flies in particular, excellent models for use in learning experiments that test a number of learning parameters. Operant

conditioning in honeybees has been the subject of extensive study over the last century, pioneered by work using free-flying target discrimination tasks (von Frisch 1914). In these tests, free-flying bees are usually given a choice between two visual targets, one of which is associated with a food reward, in an experimental design that mirrors the honeybee's natural foraging behavior. In this experimental structure, the bee chooses where to land. This behavioral action determines if it receives a food reinforcer. Such tests have allowed researchers to discover a wealth of information regarding honeybee cognition and perception, including the use of visual and olfactory stimuli, image matching, color learning, numerical cognition, and time-linked learning (Giurfa 2015).

*Drosophila* flies are also commonly used in operant conditioning experiments to study a myriad of cognitive and genetic questions. An experimental instrument called a heat box is commonly used with this species (Putz 2002). The instrument's chamber is split, where half the area is punished and half is not. Whenever the test fly enters the punished portion of the chamber, the temperature of the space is heated. When the fly leaves this area, the temperature in the box returns to normal. Flies quickly learn this association and restrict their movement to the non-punished side of the chamber. This association has been shown to be stored in long-term memory, as trained flies will still avoid the punished portions of the heat box hours after training. Experiments have produced similar results in jumping spiders (Peckmezian and Taylor 2016), where specific areas of a chamber are linked to electrical shock. In jumping spiders, stimuli are typically associated with visual cues due to their high visual acuity. When electrical shocks are paired with either a black or white stimulus, spiders will respond similarly to *Drosophila* by subsequently avoiding those areas in the future (Putz 2002; Peckmezian and Taylor 2016).

## Spatial Cognition

Animals that move through their environment need to be able to steer and find certain locations, be that a food source or the quickest path back to

their nest. Survival can often depend on the animal's ability to navigate accurately, especially when their environment is harsh and prolonged exposure to the elements could mean death. Navigation requires the acquisition and application of information in the environment that can indicate the direction and/or distance of a goal location. Often, animal navigators will collect environmental cues from multiple sources. Multiple information streams provide a further cognitive challenge: the navigator must integrate these signals before making a decision on where to go.

In the Tunisian desert, specialized foraging ants wander through the scorching and featureless terrain searching for food. These ants are active during the hottest parts of the day when they scavenge for other invertebrates that have fallen victim to the intense heat. These searching ants can travel hundreds of meters from the nest in long meandering paths before finding food. Once found, however, a forager will travel in a straight line back to the nest, a small inconspicuous hole (Fig. 2). How does this solitary ant find their nest in a featureless landscape when the intense heat makes chemical trails quickly evaporate? They accomplish this task using a navigational tool called path integration.

## Path Integration

Path integration is a cognitive process where the foraging ant acquires and combines both distance and directional cues for navigation during their search for food. When these two measurements are combined they allow the ant to keep track of their position relative to the nest's location during their trip. This is called their home vector. To measure the direction the foraging ant is facing, the ant has a sky compass that is based on cues such as the sun's location and the pattern of polarized light in the sky. In walking animals such as ants, distance estimates are collected through a step counter. These two measurements are collected, integrated, and stored during the winding outbound path until the foraging ant finds food and needs to return home. This allows the ant to constantly track the nest's location while out foraging. It then uses this collected information to accurately travel the correct distance and direction home (Fig. 2; Wehner and Wehner 1990).

**Arthropod Cognition, Fig. 2** An example of a complete foraging trip in the Tunisian desert ant, *Cataglyphis fortis*, which inhabits a salt pan environment with few landmarks. The forager's journey begins at the nest location in the bottom right corner, represented by an open circle. The thin line extending from the nest location represents the winding outbound path of the forager as she searches for food, with the small black circles marking her location at 60-s intervals. The large black circle indicates the location at which the forager found food. The thick line represents the

straight line inbound route back to the nest. The forager kept track of both its distance and direction from the nest during the outbound route through path integration, allowing for an efficient return to the nest entrance. (Image reprinted from *Insect navigation: use of maps or Ariadne's thread*, Wehner and Wehner (1990) (Fig. 4), published in *Ethology, Ecology & Evolution* by Taylor & Francis and reprinted with the publisher's permission (Taylor & Francis Ltd, <http://www.tandfonline.com>))

Honeybees are also known to use path integration to return to their nest after foraging, though the honeybee forager needs a different solution in order to estimate how far it has traveled, as counting steps is not very useful to a flying insect. To estimate flown distances, the honeybee forager records their traveled distance using optic flow. Optic flow is a visual cue resulting from the motion of objects and surfaces across the honeybee's visual field. As the honeybee moves through its environment, objects move or "flow" past their visual field. The honeybee can then use this information to estimate how far it has traveled and

combine it with the same sky-based directional cues as the ant in order to path integrate.

Even nonsocial arthropods use path integration to get to goal locations. Fiddler crabs need to defend home burrows and must remain vigilant for intruders even when they leave the burrow to feed on the open beach. If the burrow owner sees another fiddler crab trying to move into its burrow, it scurries back in a straight line to stop the intruder (Zeil and Layne 2002). The wolf spider also maintains a home burrow for safety and, additionally, to ambush prey. These spiders have shown the same distance and direction estimation

when returning to their burrows as ants and honeybees, indicating their use of path integration (Ortega-Escobar 2006).

The use of path integration is generally studied as a form of working memory, a memory type involving the short-term storing of information currently in use. The distance and direction components are compiled to give the animal a continuously updated location of its position relative to their nest, both during the outbound and inbound portions of their trip. As the animal reaches and enters its nest, the path integrator is reset to zero. Yet, work in both ants and honeybees has shown that these animals can also retain long-term memories of path integration information from previous foraging trips, allowing them to use path integration cues from these trips to return to an area if there is an abundance of food or to return to the nest from a known location after long delays (Beugnon et al. 2005).

### Landmarks and the Panorama

Path integration is merely one of the strategies in the navigational toolkits of arthropods. Individuals can also retain long-term memories of terrestrial cues in order to navigate. Research on terrestrial cues likely brings to mind the use of landmarks, but it is now believed that animals use the configuration of multiple objects in their visual field to navigate. There is now mounting evidence that these animals use the complete landmark makeup of the 360° visual scene, termed the panorama, to navigate rather than specific elements in the scene. The predominant theory on how insects and other arthropods use the panorama for navigation is by a view-based matching strategy (Collett 2010; Zeil et al. 2014). Here, stored images of the panorama are compared to the animal's current view while away from the goal location. To orient correctly to the goal, the navigator will attempt to match its current view with views it had previously stored. The resulting best visual match between the stored view and the current view gives the navigator the correct direction to their goal location.

View-based matching first requires that a navigator learn the panorama around its nest or other goal location. Nest panorama acquisition is

accomplished in honeybees and wasps through a behavior called learning flights. Before a forager first leaves the nest area, the forager slowly flies in looping arcs while facing the nest from multiple directions. Ants and spiders exhibit very similar behaviors, called learning walks, on the ground around the nest or burrow. When first leaving their nest or burrow, they will perform multiple pre-foraging trips within the nest area in looping paths that occasionally look back toward the nest direction. It is believed that during these learning flights or walks, views of the panorama around the nest are being stored for future use. Once the panorama at the nest site is learned, foragers leave the nest area, occasionally turning back to face the nest. By turning back to the nest the individuals can learn and store multiple views of the outbound route, as well as changes in the panorama for use when they need to find their way back. These stored memories are robust, allowing foragers to navigate home even after long delays.

Certain arthropod species living in environments with access to both the sky compass and terrestrial cues have shown an additional cognitive ability called cue integration, where individuals integrate information from multiple directional cues while navigating. As sky compass cues such as the sun's position are independent of the terrestrial panorama, they will not always match, leading to a cue conflict that must be resolved before a navigating animal decides which direction to go. Ants and honeybees displaced off their foraging route have been shown to average these two directional cues and choose a compromise direction between the two directions indicated by the sky compass and the panorama. This averaging ability appears to happen dynamically, as foraging ants will change how much weight they assign each cue depending on a number of factors, such as home vector length (Narendra 2007; Freas et al. 2017).

### Cognitive Maps

A more complex navigational tool thought to be in use in many vertebrate species is the cognitive map. Here, animals maintain mental

representations of the spatial layout of objects in the animal's environment. This allows animals to navigate successfully from locations they have not previously visited. The presence of a cognitive map in insect/arthropod cognition remains hotly debated in the scientific community, with skeptics contending that both path integration and view-based matching provide alternative, simpler explanations for the observed navigational abilities in arthropods. For further analysis of this topic and the debate surrounding its presence in invertebrates, please look to the cognitive map chapter of this text.

## Social Cognition

Multiple arthropod species are highly social, a characteristic commonly associated with members of the insect order Hymenoptera, which

comprises sawflies, wasps, bees, and ants. Of these, the honeybee has developed a unique behavior for communicating foraging information to hive mates in the form of dance behavior.

### Honeybee Dance

Foraging honeybees retain long-term memories of path integration cues after returning to the hive. Not only do they use this information on subsequent foraging trips, but they can also broadcast this information to other foragers. Upon returning to the hive, a successful forager will perform a dance behavior, characterized by a looping figure-8 like pattern (Fig. 3; von Frisch 1967; Grüter and Farina 2009). This dance conveys to the forager's hive mates information about both the distance and the direction of the food source they visited. The orientation of the zigzag portion communicates to observing hive mates the direction of the food relative to the sun's position, and

**Arthropod Cognition, Fig. 3** An example of the figure eight honeybee waggle dance with both the dancer (center individual) and follower bees (bottom four individuals). The dancer bee (1) performs the waggle portion of the dance, represented by the jagged line, and then turns to one side, here the left, and loops (2) back to the start of the waggle portion. At the start of the waggle portion (3), the dancer performs a second waggle run (4) and then typically

loops in the opposite direction, in this case to the right (5). This dance provides follower bees multiple pieces of information, including the direction, distance, and quality of the potential food source. (Image reprinted from *The honeybee waggle dance: can we follow the steps?*, Grüter and Farina (2009) (Fig. 1), published in *Trends in Ecology & Evolution* by Elsevier and reprinted with the publisher's permission (Elsevier Publishing, <https://www.elsevier.com/>))

the duration of the zigzag portion indicates the distance the food is from the hive.

This dance behavior also provides an example of associative learning in honeybees, albeit under natural conditions rather than under controlled experimental testing (Fig. 1). Hive mates of the dancing forager will follow behind her during the dance, and the dancer will regularly drop the scented nectar of flower patches she visited in her path (Fig. 3). This behavior allows the followers to learn the scent of the flowers the dancer successfully visited.

### Observational Learning

The dance behavior of the successful forager and the information passed on to the following foragers provides examples of two abilities seen in honeybees: functionally referential communication and social learning. Functionally referential communication denotes signals that refer to events or objects in the world, such as the successful honeybee forager signaling where a food source can be found. Social learning is the ability of an animal to learn information or behaviors from another animal, typically a conspecific (member of the same species). In this context, the observing honeybees are learning information about the spatial location of a profitable food source, yet a number of arthropods have been shown to observe and then duplicate behaviors of conspecifics in a range of contexts.

Social learning experiments commonly involve the separation of individuals into naive observers and experienced demonstrators. The observer, as the name suggests, observes, as the demonstrator, usually a trained or more experienced conspecific, performs a behavioral choice or test. When these observers are subsequently presented with the same behavioral choice or test, they are able to use information learned from the demonstrator in their own behavioral decisions. During mating, *Drosophila* females exhibit social learning by watching the mating behavior of other *Drosophila*, preferring to mate with males that have the same characteristics as demonstrator males that were observed to be successful at mating (Mery et al. 2009). This learning occurs even when the characteristics of the male flies have no influence on reproductive success.

*Drosophila* females also show social learning in their egg-laying site preferences. Females who observe other females choose between two equally profitable egg-laying sites and are more likely to choose the same site as the demonstrator for their own eggs (Battesti et al. 2012). In a foraging context, bumblebees learn which flowers are more rewarding by observing and then copying the flower preferences of other, more experienced foragers. In jumping spiders, when an observing spider watches a conspecific decline to attack a novel prey type, this spider will also show increased hesitation to attack this prey type when they experience them in the future.

Observers can even learn nonnatural behavioral tasks demonstrated by trained conspecifics. In bumblebees, in what has been described as “bumblebee football,” researchers (Loukola et al. 2017) taught individuals to drag a wooden ball to a goal area in order to receive a food reward (example of associative learning). Once the demonstrator bee was trained, it performed this task in front of an observer bee multiple times. This observer was then presented the same test where it also successfully rolled the wooden ball into the goal. This research shows that not only are these animals capable of learning complex cognitive tasks, but they can also learn behavioral patterns that are not associated with their typical behavioral routines through observing and learning from other bumblebees.

Social learning can also extend to the individual recognition of nest mates. Remembering individual characteristics of a nest mate when living in large colonies containing thousands of members appears unlikely, but some arthropod species live in small colonies where recognizing specific nest mates may be valuable. Individual recognition can also be valuable in solitary species that regularly compete with other conspecifics for resources. Individual recognition cues are commonly olfactory, with individuals remembering specific chemical cues associated with familiar conspecifics. Solitary hermit crabs learn the individual scents of previously encountered individuals and will link this scent with past experiences of that individual, specifically the quality of that conspecific's shell. In ants, unrelated queens learn the chemical cues of previously encountered queens

and regulate their behavioral response based on this familiarity (D'Ettorre and Heinze 2005). These recognition cues can also be visual; individuals learn the patterns or markings of conspecifics. Social paper wasps perform a form of individual recognition by learning the distinct black and yellow pattern on the front of conspecifics' faces, a visual cue associated with social dominance. When the facial patterns of a known conspecific are experimentally altered through painting, other individuals act more aggressively to the painted individual regardless of whether the paint created a higher- or lower-dominance signal (Sheehan and Tibbetts 2011).

### Distributed Cognition

A more recent field of cognitive study, distributed cognition, encompasses cognitive processes that reside outside of the organism's central nervous system and has been exhibited across a number of phyla, including arthropods (Cheng 2018). One variety of distributed cognition is termed embodied cognition and covers cognition that occurs in areas of the organism's body outside the brain.

### Embodied Cognition

Female crickets showcase embodied cognition in their search for mates. Male crickets attract females through the production of songs, and females are attracted to males who produce the loudest of these songs. Females find their preferred mate by receiving these auditory cues through their ears, which in crickets are located on each of the front legs. These ears are connected through a tracheal tube. This tube allows the female to detect the direction of the sound's origin. Within the structure of the female cricket's ears and tracheal tube, there are a number of interneurons, which control her turning behavior. The act of identifying the loudest male's song and its direction occurs only in the structures of the female cricket's tracheal tube and the eardrums. Once these structures have processed the incoming information, the signal goes out to the motor system for the female cricket to turn in the direction of the chosen male song. This entire process occurs wholly outside the cricket's brain.

*Drosophila* fly larvae also show evidence of embodied cognition, through the offloading of the cognitive processes associated with locomotion to nerves along their body. *Drosophila* larvae have elongated, legless bodies, yet can crawl through the environment through coordinated body movements. These larvae are constantly searching for food using these coordinated body movements, and remarkably, input from the brain is not needed for the larvae to move. When the larvae's brain is blocked from sending signals to its body, the peripheral nerves along the body of the larvae will still coordinate the necessary movements, though directed movement to goals still requires the brain (Berni et al. 2012).

### Extended Cognition

Extensions of cognitive processes beyond the central nervous system can also encompass areas beyond the organism's body, including structures or objects created by the organism, a phenomenon called extended cognition (Cheng 2018). Recent research (Japyassú and Laland 2017) has explored extended cognition in the webs of spiders, proposing that changes in web tension represent the extension of the spider's cognitive processes into its web. As a spider's hunger level increases, it will adjust the tension level of the web's threads. When the web is tightened, smaller insects will cause disturbances that draw the spider's attention. When the spider is not very hungry, having recently eaten, it will loosen the web's threads, and these same smaller disruptions no longer draw the spider's notice. Thus the spider calibrates the web as a result of its current state, and the web in turn provides different levels of feedback to the builder based on this state. This link creates a flow of information in both directions between spider and web.

### Conclusions

This chapter highlights the cognitive abilities exhibited by different arthropods. That members of this group have small brains does not limit their ability to draw upon complex behavioral repertoires across an array of contexts. Arthropods display high degrees of behavioral flexibility, with the ability to learn and retain a multitude of

cues for use over both the short and long term. These attributes make this group highly valuable to researchers interested in cognition, and unsurprisingly, arthropod species such as the honeybee and *Drosophila* fly are model species for the study of learning and memory. Though some of this research has focused on modest cognitive processes such as associative learning, this chapter has also discussed more complex cognitive processes such as extended cognition, cue integration, and social learning. The study of arthropods can provide us with an understanding of how complex cognitive processes can be achieved by organisms with limited nervous systems. Furthermore, the diversity of this phylum and the broad range of behaviors and ecology can help researchers uncover how such processes evolved.

## Synonyms

[Invertebrate food habits](#); [Invertebrate forage](#)

## Definition

An arthropod is an invertebrate animal in the phylum *Arthropoda*. The nomenclature of arthropod is a nod to the invertebrates “jointed” (arthros) “legs” (pod) (Tugel and Lewandowski 2001). Diet is simply coined as the food an individual consumes for the purposes of health and survival.

## Introduction

Arthropods do not have a backbone or internal skeleton, but instead rely on a hard outer exoskeleton made of chitin for protection. Arthropoda is a diverse phylum that includes animals such as beetles, ants, crustaceans, spiders, ticks, centipedes, millipedes, and scorpions. These animals are often soil dwellers and provide the benefit of soil aeration and mixing as they move about. Marine arthropods provide the same benefit to the ocean floor as well.

Arthropods exhibit a wide array of feeding modes such as carnivory, herbivory, detritivory (organic matter produced by the decomposition of organisms), fungal feeders, filter feeders, and parasites. These animals typically have mouthparts that are highly adapted to their feeding mode, allowing for easier capture and consumption of prey. Examples of these specialized mouthparts include: piercing mandibles for herbivorous ants, claws for crabs, lapping mouthparts for nectar intake by bumblebees, and piercing-sucking mouthparts for mosquitos (Vila 2017). Some arthropods (such as spiders and scorpions) even utilize venom when capturing prey, and this venom is usually quarantined to a specific location within the arthropod's body. For example, scorpions of the order Scorpiones use venom enclosed within the tip of their tail in capturing prey and self-defense.

The digestive system of arthropods is composed of three main parts: (1) foregut (pharynx and esophagus leading to the stomach), (2) midgut (stomach), and (3) hindgut (colon and anus) (Vannier and Chen 2007). The foregut and hindgut are composed of the same material as the

exoskeleton, and are shed along with the exoskeleton during the molt. Some components of the digestive system for arthropods are varied based on their eating mode, but the midgut generally contains the digestive enzymes that are essential for breaking down food and absorbing nutrients. The four main categories of arthropod feeding modes and relating diets are described below.

## Shredding Arthropods

Arthropods that are classified as shredders are typically larger in size and are more commonly seen on the soil surface as opposed to deep within the soil. These animals consume food by using their strong mouthparts to shred dead plant matter, while also consuming bacteria and fungi on the surface of the plant material. Decaying plant matter is the primary source of their diet. Consumption of these items is vital for nutrient cycling within the ecosystem and also aides bacteria and fungi in the soil, which act as decomposers. Common examples of arthropod shredders are: sowbugs (*Oniscus* spp.), earthworms (*Lumbricus* spp.), and millipedes (*Euryneridesmus* spp.) (Moldenke et al. 2000). In a forest setting, shredders contribute to the soil recycling pattern because when they consume dead plant material, they only absorb the most available nutrients, and the remaining materials are excreted as waste back into the soil.

Though consumption of decaying plant material by shredding arthropods has many environmental benefits, some shredder species can be problematic in an agricultural setting. Sowbugs, pillbugs, and other shredding species may cause issues for farmers if they begin to consume their growing crop. Fresh and healthy plant material is not a common dietary source for shredders, but in the absence of an abundant amount of decaying plant material, they turn to live material as a secondary food source. Termites (*Isoptera* spp.) are another common arthropod shredder that can cause substantial damage to homes and other structures. Termites feed on decaying wood

using protozoa in their gut to digest cellulosic material, such as wood (Cleveland 1923). Degradation to the wood can cause costly repairs for homeowners if undetected over time. However, termite feeding behavior is not always destructive – in a forested setting, termites break down woody debris which would otherwise be accumulated as waste in the environment.

Shredders are commonly found in the pedosphere, which means they live within the soil. This behavior is attributed to their morphological characteristics, such as their specialized mouthparts for shredding, adapted for abundant dead and decaying plant material in the soil. Ability of arthropods to navigate deep within the soil is restricted by size and other morphology. For example, sowbugs are less capable of occupying deeper soils due to their size, restricting their diet to the organic material closer to the surface of the soil. Alternatively, shredders like the desert millipede (*Orthoporus ornatus*), which can grow up to 8 in. long, can delve deeper within the soil and have greater access to a variety of food resources, such as decaying roots. The presence of these animals is an essential component of a healthy and properly functioning ecosystem, as they aerate and mix the soil through their movements, along with aiding in the nutrient recycling process.

## Predatory Arthropods

Arthropods exhibiting predatory behavior are a very diverse group, which includes but is not limited to spiders (Order Araneae), centipedes (Class Chilopoda), scorpions, crustaceans (Subphylum Crustacea), and ants (Family Formicidae). Predatory arthropods can be further broken down into two groups: generalists and specialists. Generalist predators have an expansive diet, and are not selective in making prey choices. Specialist predators are adapted to target only one or a few desired species as prey. Because of their size, most arthropod predators consume other invertebrates. However, there are some predatory arthropods that are large enough to consume vertebrate animals, such as spiders and

certain crustaceans. One well-known example of this is the Goliath birdeater tarantula (*Theraphosa blondi*), which is considered a generalist predator. This arthropod is native to South America and weighs up to six ounces. It is considered an ambush predator, hiding behind rocks or in shallow burrows waiting to ambush unsuspecting prey. As denoted by its name, this tarantula on occasion consumes bird eggs or young birds, but it will also eat beetles, earthworms, rodents, toads, bats, lizards, snakes, and other prey opportunistically (Striffler 2005). Crustaceans, such as lobsters (Family Nephropidae), are another example of a generalist predator, consuming clams, mussels, fish, crabs, and at times, other lobsters. It is common for generalist predator arthropods to consume other types of arthropods, such as shredders or herbivorous arthropods, and even on occasion other predatory arthropods. Arthropods exhibiting specialist predatory behavior are less common than their generalist counterparts. Even more rare is a true monophagous predator, which means that the predator only targets a single prey resources. A spider from South Africa, ammxenus termite feeder (*Ammoxenus amphalodes*), is one of the few examples of a true monophagous predator. It has been shown in a replicated laboratory setting that *A. amphalodes* would not accept, nor even attempt to capture any other prey source other than the termite species, African harvester termites (*Hodotermes mossambicus*) (Petráková et al. 2015). Another example of a loosley monophagous predator is the goldenrod crab spider (*Misumena vatia*). This spider does not weave an intricate web and wait for prey to become entangled; instead it hides within a flower and waits to ambush prey of a few target taxa. A common colloquial name for this spider is “the flower spider” due to the fact that it hides within the center of a flower, typically the goldenrod flower, camouflaging itself within the golden yellow center. Then when an unsuspecting bee or wasp comes to the center of the flower, the spider uses its long front legs and bite to immobilize its prey (Heiling et al. 2004). It is also widely known to change color to match the flower color it is hunting from as a form of crypsis.

## Herbivorous Arthropods

Herbivorous arthropods are numerous, and often they are considered pests in cropland areas. It is currently estimated that approximately one million phytophagous (feeding on plants) insect species rely on plants as their only food source (Jander and Howe 2008). These arthropods consume both aboveground and below ground plants and commonly consume roots. Examples of herbivorous arthropods are: cicadas (Superfamily Cicadoidea), crickets (Superfamily Grylloidea), root-maggots (Family Anthomyiidae), and rootworms (*Diabrotica* spp.). The mode of feeding employed by these arthropods is based on their mouthparts, and there are four different categories: leaf chewers, leaf miners, gall makers, and piercing/suckers (Buddle 2012). As denoted by their name, herbivorous arthropods consume plants, but they are not just limited to leafy foliage; these arthropods consume all plant parts, such as: leaves, flowers, roots, fruits, xylem, and phloem.

In recent years several herbivorous arthropod species have shifted more into a “pest” role. This is caused by the urbanization of previously natural areas, such as fields and small forested areas. Homeowners will often combine a mixture of ornamental lawn decoration and natural vegetation to adorn their houses, which may attract herbivorous arthropods that consume the ornamentals. One example of this is the increased levels of generalist herbivores like spider mites (*Tetranychid* spp.) in urban areas, which cause damage to plants by puncturing the plant cells (Raupp et al. 2009). As with most scenarios, vegetation is a vital driver for biodiversity, meaning that with an increase in vegetative diversity in the area, there is also an increase in the biodiversity of herbivorous arthropods in the area.

The diet of herbivorous arthropods is expansive and inclusive. This is often the root of the issue with crop damage in agricultural settings, as the herbivorous arthropods are difficult to control, and damage is often caused by more than one species. The garden symphylan (*Scutigera immaculata*) is a soil dwelling arthropod related to the centipede who feeds on subterranean plant

parts and seedling roots. As a result of this feeding, plants have poor vigor, growth, and survival rates. These arthropods cause prominent damage in agricultural fields, impacting crops such as: broccoli, beets, onions, carrots, corn, spinach, and squash. Due to their size and mouth part limitations, smaller seeds and seedlings are more susceptible to predation by symphylans than larger seeds/seedlings. In combination with commercial pesticides used to commonly control insect pests, tillage of the soil is also used to control garden symphylan populations in agricultural soils.

### Fungal Feeding Arthropods

The final category of arthropod feeding contains the fungal feeders. These subterranean arthropods are generally soil dwellers that consume fungi and (a small amount) of bacteria off of vegetative root surfaces. Examples of arthropod fungal feeders include the hairy fungus beetle (*Typhaea stercorea*), springtails (Subclass Collembola), certain mites, and silverfish (*Lepisma saccharina*) (Shetlar 2011). There are several factors that will impact the presence of arthropod fungal feeders within the soil such as root biomass, microfungi diversity, hyphal (filamentous structure on fungi) length, temperature, water content, pH, organic matter content, and many others (Klironomos and Kendrick 1995). Though many of the arthropods in this category are microscopic soil dwellers, there are some larger ones that move around on leaf surfaces above the soil surface and consume fungi residing on plant leaves. This is a vital ecosystem service provided by the arthropods because fungus on the plant surface is often mixed in with beneficial bacteria. In the process of feeding, the arthropods disturb, consume, digest, and excrete beneficial bacteria within soil. From there, the nutrients within the waste are further broken down and redistributed by other microorganisms in the soil. This distribution increases the soil's fertility and its ability to store nutrients.

There are hundreds of types of fungi and bacteria consumed by fungal feeding arthropods, but what they have in common are the physiological parts of the fungi that are ingested. The two main components of fungi eaten by fungal feeding arthropods are: hyphae and spores (Basset 1991). The fruiting body (mycelium) is the main bulk of the fungus, and it is made of fine filamentous network of hyphae. Fungal spores are single celled reproductive units representing functional organisms that are capable of producing new fungi without any other outside components.

As with most other species of arthropods, fungal feeders are present in urban areas and are oftentimes considered pests by homeowners, despite their environmental benefits. Silverfish will commonly infest older homes, especially those with unknown mold infestations or older amounts of decaying material (i.e., vintage books or clothing collections). These areas frequently contain fungi as well as palatable carbohydrates, providing abundant feeding grounds for silverfish (Lindsay 1940). Springtails are another common nuisance species, as they are found in high moisture areas and can appear in or around a household after times of extreme flooding or an unexpected leak.

### Conclusion

Though their presence in urban areas is often viewed as an annoyance, arthropods bring about more benevolent circumstances than harmful ones with their invaluable role in transferring nutrients within the ecosystem. Shredding arthropods are vital ecosystem recyclers, aiding bacteria in the decomposition process and continually renewing the soil, which in turn results in healthier plant material. Though many are coined as a nuisance in urban areas, predatory arthropods are an indispensable form of natural pest control within the environment. A key example of this is spider species consuming pest species such as mosquitos, which can harbor dangerous diseases. Herbivorous arthropods are often threats to agricultural

lands, and they do cause destruction and damage to crops, but they are an integral component of the food chain, not only providing food to higher orders but also to other arthropods as well. Lastly, fungal feeding arthropods perform a role similar to that of shredding arthropods. The difference being that fungal feeding arthropods consume and excrete fungal waste, aiding in the breakdown of microorganisms in a more complex way than shredding arthropods, and increasing soil nutrient content and fertility.

## Arthropod Life History

Kenneth James Chapin

Department of Neurobiology, Physiology, and Behavior, University of California, Davis, Davis, CA, USA

### Definition

The changes undergone by an arthropod during its lifetime.

### Introduction

Arthropods account for over 80% of the species on earth. As such, the diversity of life histories of arthropods practically spans that of all life. Arthropods are born, grow to sexual maturity, reproduce, and die; discovering variation and patterns of these major life events is to study life history of arthropods (Stearns 1992).

There are four major groups of extant arthropods. Chelicerates (>100,000 species) include animals like spiders, mites, harvestmen, and the four extant species of horseshoe crab; Crustaceans (>70,000 species) include groups like crabs, shrimp, barnacles, woodlice, and brine shrimp; Myriapods (>16,000 species) include centipedes and millipedes. The most speciose group, insects (>2 million, and perhaps as many as 30 million), includes beetles, butterflies, flies, and bees, among many others. Extant arthropods range in size from the crustacean giants to maxillopod miniatures. The Japanese spider crab is the largest of all arthropods with a 2.8 m leg span and the American lobster is the heaviest, weighing over 20 kg. Coconut crabs are the world's largest terrestrial arthropods, weighing over 4 kg, and with a 1 m leg span. Tantulocarida – highly specialized parasitic crustaceans – includes the smallest arthropod species, measuring only 85  $\mu\text{m}$ . This vast richness of life presents a variety of life histories, which are discussed below.

## Reproduction

Most arthropods reproduce sexually in a bisexual population. Like all things in arthropod life history, however, there are interesting exceptions. Some species (e.g., most barnacles) are hermaphroditic, such that a single individual has both male and female sexual organs (Charnov 1987). These species often mate with other individuals, but self-fertilization can also occur (Yusa et al. 2011). Other species are parthenogenic (e.g., some bees and scorpions), where unfertilized ova develop without sperm.

Nevertheless, most arthropod species need to find a mate and transfer sperm to reproduce. Arthropods can have internal or external fertilization, depending on the species. Aquatic arthropods may release gametes into the water column, where sex occurs externally. All terrestrial arthropods, and many aquatic species, engage in internal fertilization, where sperm are inserted into the reproductive tract of the female by some mechanism. The most common mechanism for internal fertilization is the spermatophore, a packet of sperm deposited by the male and retrieved by the female (Proctor 1998). The simplest form of spermatophore deposition occurs when males leave spermatophores in the environment for females to find. Alternatively, courtship rituals can be used to direct females to the spermatophore, which may be deposited on sclerotized (hardened cuticle) stalks (Weygoldt 2000). Further, spermatophores may be deposited directly into the female via a variety of organs, including pene and gonopores (Macías-Ordóñez et al. 2010). Females of many species have mechanisms to store sperm for multiple clutches, or divert it away from eggs to avoid fertilization from an unsuitable male (Andersson 1994). Spermatophores can include nutrients to support offspring survival, or hormones to change female behavior (Gillott 2003; Vahed 1998).

Arthropods may be semelparous or iteroparous (one vs. multiple reproductive events). Some species produce a single clutch of eggs before senescence, while others produce multiple clutches in a season, year, or across multiple years. Arthropods can produce very few to thousands of offspring

per reproductive event. According to life history theory, arthropods, like all organisms, should maximize reproductive fitness by optimizing the relationship between the quality and quantity of offspring. Some arthropods, like Theraphosid spiders, produce hundreds of tiny offspring, of which only a small fraction survive to adulthood. Still other arthropods, however, produce very few young (e.g., some tsetse flies produce only a single egg; Tobe and Langley 1978). Variation in offspring number and size is also in part explained by environmental variation, with substantial variation occurring within species (Fox and Czesak 2000).

## Parental Care and Sociality

The level of parental investment varies in arthropods more than any other group. Forms of postzygotic parental care include nest and burrow building, territoriality, caring for eggs, caring for young after hatching, and provisioning young with food, even after offspring are independent (Clutton-Brock 1991; Trumbo 2012). Notable behaviors include exclusive paternal care seen in many harvestmen (Opiliones) – only the male contributes postzygotic resources (Tallamy 2000; Pinto-da-Rocha et al. 2007). Many arthropod species engage in matrophagy (>3000 species; Ostrovsky et al. 2016), where offspring consume a parent (usually the female) to increase offspring survivorship, and presumably, parent inclusive fitness (Ostrovsky et al. 2016). Most scorpions carry offspring on their dorsum for protection, and may even provide food to young (Polis 1990).

Parental care is one of the two evolutionary routes to sociality (Bourke 2011). In the most basic sense, an offspring receiving care from one or both parents is a social group. Social groups lasting longer than this initial period have evolved in many Arthropod groups. Groups made up of relatives are termed fraternal groups, while groups made up of nonrelatives are termed egalitarian groups (Bourke 2011). Fraternal groups include the social bees, wasps, and ants (of the order Hymenoptera), termites, and some species of beetle, true bugs, and thrips, all of which form large

colonies with one or a few reproductive individuals. This reduction in reproductive individuals insures genetic relatedness among colony mates. Some species of spider form large fraternal groups, but, unlike social Hymenoptera, have little skew in reproduction across individuals of a colony. Instead, colonies maintain high relatedness by inbreeding (Bilde et al. 2005; Agnarsson et al. 2006). As mentioned, egalitarian groups are social groups composed of nonrelatives. Examples include arthropods that group around a resource like spiny lobsters, harvestmen, or amblypygids that aggregate around high-quality microhabitat (Zimmer-Faust and Spanier 1987; Machado 2002; Chapin 2014).

## Birth and Growth

All arthropods are born from eggs, although ovoviviparity, in which eggs hatch inside the mother, which then gives birth to free-living young, occurs in some species (scorpions, in particular). Eggs can be deposited into the environment (water column, on vegetation), in a built structure (burrows, silk chambers), or are carried by the female.

Arthropods grow by molting a sclerotized exoskeleton (Gilbert and Frieden 1981). Many arthropods have a series of molts, the last of which results in sexual maturity, and, in the case of insects, wings. Thus, arthropods not only increase their size with successive molts, but also change morphologically as they develop into adult forms. These growth patterns are often binned into three categories, based on the level of change that occurs during development: ametaboly, hemimetaboly, and holometaboly. Ametabolous (sometimes termed direct development) arthropods maintain general morphology from hatchlings to adulthood. All myriapods, bristletails, and silverfish, for example, exhibit this form of development. Many arthropods engage in hemimetabolous development (sometimes termed simple or incomplete metamorphosis), which has three stages (egg, nymph, and adult) and more minor changes in morphology than complete metamorphosis. Examples include insects like

true bugs, crickets, and cockroaches, which have young that generally resemble adults, but without wings or reproductive organs.

The most complex form of metamorphosis is holometaboly, also called complete metamorphosis. Holometabolous arthropods exhibit four developmental stages: egg, larva, pupa, and adult. Eggs hatch and the larva (e.g., caterpillars, maggots, and grubs) undergo several molts before entering the pupa stage, during which the arthropod is usually inactive. After some time, the adult molts from the pupa, usually with notable morphological differences from the juvenile form. Holometabolous arthropods include butterflies, beetles, and flies. An estimated 45–60% of all living species are holometabolous insects (Hammond 1992). Some arthropods, like Amblypygi and female Theraphosid spiders, have postultimate (after-maturity) molts (Chapin and Hebets 2016). These species also tend to have extended lifespans, and multiple reproductive events.

## Conclusion

Arthropods make up the majority of Animalia and, thus, represent the enormous variation in life histories. Adapted life histories range from living hours to decades, producing a few to thousands of offspring, and providing little to huge offspring benefits. The diversity that Arthropoda captures is exceptional, and so is the life history of animals in the world's largest phylum.

### Definition

Arthropods are the invertebrates that constitute the largest group of the animal kingdom. These animals can be easily recognized and differentiated into different types due to their distinct external body appearance or morphology. An arthropod's morphology features include an exoskeleton, paired jointed appendages, and a segmented body.

### Introduction

The phylum Arthropoda (in Greek, *arthros* means jointed and *podos* means foot) is the largest and presumably the most variegated group in the

animal kingdom. The most remarkable adaptive diversity of arthropods helps them survive in every habitat, such as marine, freshwater, terrestrial, and aerial. They are found to be the most successful invaders of the terrestrial habitat on the earth. More than 800,000 species have been described. Thus, Arthropoda is approximately 80% of all known animals (Ayyar and Ananthakrishnan 1994).

This group is of particular interest to mankind as many of the members are economically significant. On the one hand, many members such as prawns, lobsters, shrimps, and crabs contribute to man's food supply; others pollinate flowers, destroy pests, supply useful products (lac, silk, honey, etc.), and provide other valuable services. On the other hand, many insects destroy crops, food stores, household goods, clothing, furniture, etc.; inflict injury as parasites; and transport organisms of dreadful diseases to man and his livestock. Arthropods are thus directly or indirectly concerned with the health, wealth, and prosperity of humanity.

### General Characteristics

Arthropod's body is bilaterally symmetrical. Their body parts are arranged like a mirror image of one side to the other. The body is metamERICALLY segmented, where the segmentation is noticed right from the anterior to the posterior axis. These segments are known as metameres or somites (Hickman et al. 2003).

The body is covered with an exoskeleton made of the chitinous cuticle, which is often thick and hard, but in places on the trunk and limbs, it is flexible to provide movable joints. The exoskeleton forms armor for protection and prevents the loss of water; this has enabled Arthropoda to invade the land. The chitinous covering or exoskeleton is cast off and renewed periodically, and the growth of the animal takes place during the intervals. This process is known as ecdysis or molting (Hickman et al. 1988).

Typically, each segment of the body bears a pair of appendages that are also segmented, with the joints' soft membrane. A segment of the limb

is termed a podomere. This jointed nature of the appendages is implied in the name Arthropoda. The appendages are variously modified in the different groups of the phylum Arthropoda and the body's various parts in the same animal as legs, gills, jaws, etc. Cilia are absent from all parts of the body.

Sense organs include antennae and sensory hairs, compound eyes and ocelli, auditory organs, and statocysts. Sexes are separate and sexual dimorphism is commonly seen. Internal fertilization occurs, and the development is direct or indirect with larval stages.

## Classification

The phylum Arthropoda is divided into three significant subphyla: Trilobitomorpha, Mandibulata, and Chelicerata (Brusca and Brusca 2003; Miller 2005).

### Subphylum Trilobitomorpha (Gk., Tri = Three + Lobos = Lobe)

They were reported abundant during the Cambrian and Ordovician periods (440–550 million years) and disappeared at the end of the Permian period (around 260 million years ago). All extinct marine forms were mostly bottom dwellers with a body size ranging from 2 to 67 cm in length. The name indicates a trilobed body caused by a pair of longitudinal grooves. The body was depressed and consisted of the head (cephalon), middle thorax, and posterior pygidium. The thorax and pygidium together form the trunk. The head has a pair of antennae, a pair of compound eyes, a mouth, and four pairs of jointed appendages. Each body somite except the last possesses a pair of biramous (two-branched) appendages on the ventral surface. Although pygidium possesses segmental appendages, its segments are fused, for example, *Dalmanites* and *Triarthrus* (Fig. 1).

### Subphylum Chelicerata (Gk., Chele = Claw + Keras = Horn + Ata = Group)

Chelicerates encompass animals such as spiders, scorpions, horseshoe crabs, ticks and mites, sea

**Arthropod Morphology, Fig. 1** Triarthrus

spiders, and sea scorpions (extinct). The body is divided into an anterior cephalothorax (prosoma) and a posterior abdomen (opisthosoma). Chelicerates are the only group of arthropods without antennae and mandibles. They have (a) six pairs of appendages, including a pair of chelicerae (for grabbing and shredding food, hence the name Chelicerata); (b) a pair of pedipalps; and (c) four pairs of walking legs (except in horseshoe crabs where a pair of chelicerae and five pairs of walking legs are seen). This subphylum has been divided into three classes:

#### Class Merostomata

This includes marine forms, and only four species are currently living, for example, *Limulus* (horseshoe crab) (Fig. 2). Their body is dorso-ventrally flattened. Prosoma is protected with a carapace of horseshoe shape. It has three longitudinal ridges (one median and two lateral), paired ocelli, compound eyes, and ventrally located mouth. The appendages around the mouth are a pair of chelicerae, four pairs of chelate legs for locomotion and mastication, and one pair of the non-chelate leg for digging. Opisthosoma is movably articulated with the prosoma, and it consists of six segments with lateral spines and a telson (caudal spine). The opisthosoma also bears six pairs of appendages.

**Arthropod Morphology, Fig. 2** *Limulus*

#### Class Arachnida

This includes many familiar organisms like spiders, scorpions, mites, and ticks. Their prosoma bears six pairs of appendages, but opisthosoma is usually without appendages, for example, scorpion (Fig. 3). *Palamnaeus*, the common black scorpion, has an elongate body and grows up to 10–15 cm. The segmented body is divisible into a short anterior prosoma, middle mesosoma, and posterior metasoma. The carapace bears a pair of median eyes close to the middle line and two or three pairs of smaller lateral eyes in the anterolateral margin. Prosoma possesses six pairs of appendages, one pair of the small chelate chelicera, one pair of large chelate pedipalps, and four pairs of walking legs. Mesosoma and metasoma are apodous. The last five segments of metasoma constitute the “scorpion tail.” Behind the last segment of the metasoma lies the postanal sting with a vesicle and spine.

#### Class Pycnogonida

This includes marine chelicerates known as sea spiders. They are not spiders, but the name sea spider is based on superficial similarities such as eight long legs and a small body. Pycnogonids are commonly small animals, and their body length mostly varied from 1 to 10 mm, but deep-sea species may attain a length of more than 6 cm, for example, *Nymphon* (sea spider) (Fig. 4). The body is usually narrow and tubular with three regions – the head (cephalon), trunk, and abdomen. Cephalon bears two pairs of ocelli and at its

**Arthropod Morphology, Fig. 3** Scorpion

**Arthropod Morphology, Fig. 4** *Nymphon*

anterior end a cylindrical proboscis with a mouth at the distal end. The appendages of four-segmented cephalons are mainly one paired chelicerae, one pair of pedipalps, one pair of ovigerous legs (egg-carrying legs), and one pair of walking legs. The trunk is composed of three segments and carries three pairs of long walking legs. The rudimentary abdomen possesses no appendages but an anus.

#### Subphylum Mandibulata (L., Mandibula = Mandible + Ata = Group)

All mandibulates have mandibles on the third head segment for chewing or grinding food. The body can be divided into the head, thorax (or cephalothorax), and abdomen. Appendages of the head consist of one or two pairs of the antenna, a pair of the mandible, and one or two pairs of the maxilla. Members of this subphylum include freshwater, marine, and terrestrial forms. This subphylum has six classes:

### Class Crustacea (L., Crusta = Shell)

A chitinous exoskeleton covers the body. Head appendages are paired antennules, antennae, mandibles, and two paired maxillae. Paired biramous appendages are seen on each segment of the thorax and abdomen. Crabs, prawns, lobsters, water fleas, and barnacles are coming under this class, for example, marine prawn (*Penaeus*) (Fig. 5). The elongated and more or less spindle-shaped body can be divided into a cephalothorax (fusion of the head and thorax) and abdomen. The body consists of 19 segments, and each segment carries a pair of appendages. Appendages are also segmented, and these segments are called podomeres. Cephalic appendages are composed of five pairs: paired antennule, antenna, mandible, first maxilla, and second maxilla. Thoracic appendages are eight pairs. The first three pairs are specialized for feeding and are called maxillipeds or foot jaws. The succeeding five pairs are walking legs. Abdominal appendages, known as pleopods or swimmerets, are of six pairs and are used for swimming. The first pair of pleopods is varied in males and females. The second to fifth pairs are typical. The broad and flat sixth pair is known as uropods.

### Class Chilopoda (Gk., Cheilos = Lip + Pous = Foot)

The members of this class are commonly known as centipedes (centi = 100 + ped = foot). The number of legs varies from 15 to 191 pairs. They are

terrestrial carnivorous with a dorsoventrally flattened body. The body can be divided into a head and many-segmented trunks. The head bears antennae and three paired jaws, namely, mandibles, first maxillae, and second maxillae. The trunk is many-segmented, and each segment carries one pair of uniramous walking appendages. The legs of the first trunk segment are maxillipeds (forcipules). These are enlarged and modified as poison claws. The anal legs on the last trunk segment are not locomotory and are variously modified, for example, *Scolopendra* (Fig. 6).

### Class Diplopoda (Gk., Diploos = Double + Podos = Foot)

Diplopods are commonly known as millipedes. They vary in size (2 mm to 30 cm). Their exoskeleton is heavily calcified. The body is long and cylindrical with a head and multi-segmented trunk. The head bears one pair of short antenna, one pair of the mandible, and one pair of the maxilla. The maxillae of the two sides are fused to form a gnathochilarium that resembles insects' labium. Externally, the trunk consists of a series of the segment like cuticular rings, and most of these rings are diplosegments. Most diplosegments possess two paired legs (Diplopoda) and spiracles. Many of them possess special glands called repugnatorial glands or stink glands that produce

**Arthropod Morphology, Fig. 5** *Penaeus*

**Arthropod Morphology, Fig. 6** *Scolopendra*

**Arthropod Morphology, Fig. 7** *Spirostreptus*

an irritating fluid on disturbance, for example, *Spirostreptus* (Fig. 7).

**Class Symphyla** (Gk., Syn = Together + Phylon = Tribe)

Members of this class are commonly known as centipedes. The body is soft and small, 2–10 mm long, and made of the head and trunk. The head bears paired antenna, mandible, a first maxilla (long), and a second maxilla (fused to form labium). The eyes are absent, but the sensory organ (Tomosvary organ) is well developed at the antenna's lower end. The trunk bears 14 segments covered by 15–24 tergites. Trunk segments 1–12 bear walking legs, segment 13 bears a pair of spinnerets, and the last segment bears a pair of sensory structures called trichobothria. The trunk terminates in a tiny telson, for example, *Scutigera* (Fig. 8).

**Class Pauropoda**

Pauropods are minute animals ranging from 0.5 to 2 mm in length. The body is divisible into a head and trunk. The head bears one pair of antenna, one pair of the mandible, and one pair of the maxilla. The eyes are absent, but pseudoculi (a pair of the peculiar disc-like sensory organ) are present. The antenna is six-segmented and three branched (trifid), a feature that distinguishes pauropods from all other tracheates (insects, centipedes, millipedes, and symphylans). The trunk contains

**Arthropod Morphology, Fig. 8** *Scutigera*

**Arthropod Morphology, Fig. 9** *Pauropus*

11 segments and a telson, for example, *Pauropus* (Fig. 9).

**Class Insecta**

These are commonly terrestrial and aerial and seldom aquatic. The body is divisible into a head, thorax, and abdomen. The head consists of six segments fused together in the adult. The head is with paired compound eyes, ocelli (up to three unpaired), and antenna. Mouthparts are suitably modified for biting sucking, siphoning, chewing, piercing, etc.). They have three-segmented thoraces with a pair of legs on each segment and pair of wings on the second and

**Arthropod Morphology, Fig. 10** Butterfly

third segments. But some insects are wingless, and some others have only one pair of wings. The abdomen is usually composed of 9–11 segments and a telson. The abdomen is devoid of appendages in the adult, for example, butterfly (Fig. 10) and stick insect.

#### **Subphylum Onychophora (Gk., Onych = Claw + Phor = To Carry/Bear)**

They are soft-bodied (hence called velvet worms) wormlike terrestrial animals with numerous paired segmented appendages. The head is not well marked off from the trunk, and it bears one pair of antenna, one pair of the mandible, and one pair of the oral papilla. The trunk consists of 13–43 pairs of trunk appendages, and these appendages are uniramous, short, stumpy, unjointed, conical, and fleshy called lobopods. Each lobopod terminates in a pair of sclerotized claws (hence the name Onychophora), for example, *Peripatus* (Fig. 11).

#### **Conclusion**

The phylum Arthropoda is the largest phylum in the animal kingdom. Segmentation of the body is the characteristic of this phylum. The head consists of the antennae, eyes, and mouth parts. Some trunk segments are often fused with the head to form the cephalothorax in the Crustacea and Arachnida. The number of segments forming the thorax and abdomen varies in the different classes.

**Arthropod Morphology, Fig. 11** *Peripatus*

In all Arthropoda, except *Peripatus*, the body is covered with a thick cuticle and forms an exoskeleton, giving protection to the body and serving the muscles' attachment. Arthropoda's eyes except *Peripatus* are simple eyes (ocelli) and compound eyes (faceted eyes). Statocysts are present in many crustaceans as organs of balancing. Sexes are generally separate. Development is always accompanied by metamorphosis.

<sup>2</sup>Department of Wildlife, Fisheries and Aquaculture, Mississippi State University, Mississippi State, MS, USA

### Synonyms

Crustacean exploration; Insect movement; Insect navigation

### Definition

The mechanisms by which arthropods maneuver to and from resources, such as shelter, food, and breeding grounds.

### Introduction

Animals in the order Arthropoda include crabs, bees, ants, and any insect or invertebrate with an exoskeleton. Arthropod navigation is a mechanism by which arthropods maneuver through their environment and locate resources necessary for survival and reproduction. Arthropods exhibit four primary types of navigation, including path integration, spatial memory, image matching, and map-like behavior.

### Path Integration

In path integration an animal tracks the sequence of movements, direction, and distance traveled and can use that information to orient to a place of origin. Path integration is also known as dead reckoning, which is better used when no landmarks are present. Path integration has been

shown to be an important navigational tool in cataglyphis ants like the desert ant (*Cataglyphis* spp.), which inhabit barren terrains (Wehner and Mandyam 1981; Wehner and Wehner 1990). On unfamiliar ground, path integration is the only available means of navigation in many arthropod species (Collect and Collect 2000). In familiar surroundings, however, guidance by landmarks may override guidance by path integration, with individuals using path integration as a secondary navigation strategy when landmark navigation fails (Collect and Collect 2000).

### Spatial Memory

Spatial memory is a fundamental cognitive faculty in many species. Studies of animal spatial memory often provide a proxy model for human memory due to the ability to transfer experimental paradigms among species (Birds and Burgess 2009). Insects will use spatial memories to help hold a position in air, to return to safety, and/or to forage location (Collect et al. 2013). Spatial memory allows the insect to recall spatial location which may be passed onto offspring through information sharing mechanisms.

### Image Matching

Image matching allows the arthropod to recall previous landmarks and make a comparative determination of whether the individual has experienced that landmark on a previous occasion. Egocentric navigation can be found when an individual uses image matching to rely on information continuously collected en route and then uses the process of path integration to integrate all angles and distances navigated to determine a mean home vector (Wehner et al. 1996). For example, the image of the horizon skyline surrounding the nest entrance is

retinotopically stored in some arthropod species and is recalled when the animal approaches the goal along its vector course. Specific locations are pinpointed by a form of image matching whereby the insect navigates to maximize the fit (i.e., reduce the visual discrepancy) between the retinal image and its memory of surrounding landmarks related to its goal (Collect 1992).

## Map-Like Behavior

Map-like behavior is the reliance on site-specific information rather than information that has been collected by coming and going continuously. Map-like behavior is considered geocentric, centering navigation on the earth's position. An arthropod exhibits geocentric (map-based) navigation when it has the capacity to determine its spatial position within the larger environmental framework (Wehner and Wehner 1990).

## Conclusion

Studies on arthropod navigation have aided scientists in understanding movement mechanisms that arthropods use to locate shelter, forage, and other features important to survival and reproduction. Yet comprehensive understanding of arthropod navigation is still not fully developed and will be important in a changing environment. Environmental changes resulting from climate and weather extremes may pose difficulties for arthropod navigation if the landscape is substantially altered.

Scotland, UK

<sup>2</sup>University of Lausanne, Lausanne, Switzerland

### Definition

An artificial fruit is an experimental apparatus which functionally mimics natural food items, where an outer shell or casing must be removed via manipulation in order to access an edible core or kernel.

### Artificial Fruits and the Two-Action Method

The term “artificial fruit” was first used by Whiten et al. (1996) to describe an apparatus provided to both human children and chimpanzees (*Pan troglodytes*). This apparatus built upon the “two-action method,” first used by Dawson and Foss (1965) in their study of observational learning in budgerigars (*Melopsittacus undulatus*). Two-action tasks expose naïve “observer” animals to “demonstrator” or “model” animals which operate on a task designed to be dealt with in either of two (or potentially more) alternative ways. The observer animals are then given access to the task, and the ways in which they interact with it are recorded. If observer animals tend to manipulate the task using the action modelled by the demonstrator more frequently than the alternative action, this indicates that social learning occurred. This method allows researchers to distinguish low-fidelity forms of social transmission, such as *stimulus enhancement* (in which animals learn to orient their behavior towards a particular object) from higher-fidelity forms of social transmission, such as *imitation*, in which an animal learns the form of a behavior through observation. Low-fidelity social transmission within a two-action artificial fruit task would lead to observers being

attracted to the apparatus more than control individuals who saw no model, but then solving the task by trial-and-error, so this would not result in animals matching the demonstrator’s solution more frequently than the alternative action.

Although two-action artificial fruit tasks identify relatively high-fidelity social learning, they do not necessarily differentiate *imitation* (copying the form of actions, like sliding versus lifting a door) from *emulation* (copying the results of actions, such as “the door slides” versus “the door rises,” which could be achieved using actions different to those observed). Alternative methods, such as *ghost controls*, can be used to distinguish between these relatively high-fidelity forms of social learning.

Artificial fruits can incorporate multiple barriers, each of which may be removed in different ways in order to access a reward, thus exemplifying the two-action method. For example, Whiten et al.’s (1996) task featured bolts which could be removed using either a poking or twisting action, a barrel latch incorporating a pin that could be removed using either a turning or spinning action and a handle that could be turned or pulled upwards. However, artificial fruits do not necessarily require high levels of manipulative complexity; some designs have incorporated barriers as simple as a door which could be either lifted up or slid to one side to access a food reward within a box (e.g., the “doorian,” Horner et al. 2006).

While retrieving the food from within all artificial fruits requires physical manipulation of the task, the first artificial fruits did not generally require the use of tools. More recently, the term has also been used to describe tasks requiring tool use. Though some of these tool-use tasks (e.g., the “Pan-pipes,” Whiten et al. 2005) require forms of behavior that are perhaps more analogous to wild primate behaviors such as termite-fishing or honey-dipping, rather than fruit processing (and so perhaps might be better termed “artificial foraging tasks”), they fulfil the same goal of providing a manipulative task that can be solved using one of at least two distinct behaviors, and so can be broadly described as “artificial fruit approaches.”

## Applications

Artificial fruits have primarily been used to examine social learning processes in both humans and nonhuman animals but have also been incorporated in experimental paradigms examining cognitive abilities such as behavioral flexibility and planning (e.g., Miyata et al. 2011). Within the field of social learning, artificial fruits have been used in dyadic settings to investigate the capacity of multiple species, including great apes (chimpanzees: Whiten et al. 1996, gorillas: Stoinski et al. 2001, orangutans: Custance et al. 2001), and other nonhuman primates (marmosets: Caldwell and Whiten 2004, capuchin monkeys: Custance et al. 1999), birds (keas: Huber et al. 2001), and human children (e.g., Whiten et al. 1996), to engage in high-fidelity social learning. They have also been used to study social learning biases (such as from which models animals are most likely to learn, and the impact of context upon such biases) and the social dynamics which affect the transmission of behaviors within groups.

## Definition

Artificial selection is the modification of desirable phenotypes in plants and animals through its propagation in the successive generation by human intervention.

## Introduction

Artificial selection is the process by which natural variations that are advantageous from the perspective of humans are selected unnaturally

or artificially. Charles Darwin discussed the concepts of artificial selection as domestication in his classic monograph *On the Origin of Species by Means of Natural Selection* in 1859 (Darwin 1859). Later, in 1868, he published a two-volume work *The Variation of Animals and Plants Under Domestication* devoted entirely to the process of domestication that he had discussed in the *Origin of Species* (Darwin 1868). His publication presented concepts and examples about the plant and animal breeding as well as the analogy between the artificial selection and natural selection. According to Darwin, artificial selection operates in similar way as natural selection and can produce concrete results if effectively applied. Darwin conceptualized selection into three types as natural selection, methodical artificial selection, and unconscious artificial selection (Gregory 2009). Methodical artificial selection is the deliberate or intentional enhancement of the desired trait of interest, while the unconscious selection refers to the passive form of artificial selection in which humans naturally preserve the desired trait without any intention of altering it and thus may result in long term effects in phenotypes unknowingly. Natural selection, as compared to artificial selection, is an environmentally driven selection of individuals possessing more advantageous traits as compared to less advantageous traits. The reproductive success of individuals is independent of selective breeding or domestication by humans.

There are several approaches to carry out the artificial selection experiments (Fry 2003). One of the most common approaches to carry out artificial selection is the traditional breeder's approach. The method employs the measurement of phenotypic traits of interest among individuals of a population and the propagation of extreme values of phenotypic traits of interest to the next generation by breeding. The process of artificial selection depends on the method, strength, and consistency of the selection (Fuller et al. 2005). The artificial selection experiments performed in the laboratory play an important role in the study of the history of evolution, adaptation process, mechanisms of genetic variation, and several

other evolutionary processes involving trade-off, mutation rate, and frequency-dependent selection. The study of artificial selection in the laboratory is a valuable tool to study genetic parameters of traits such as covariance, correlation and regression in a natural population, and their effects on fitness. Such kind of experiments are performed in the laboratory by experimenter by selecting individuals with the specific traits and propagating it along the generation or by causing the selection indirectly by fixing the environmental factors instead of direct breeding (Hill and Caballero 1992).

## Responses to Artificial Selection

The response to artificial selection is predicted by the equation  $R = h^2S$  in evolutionary biology (Falconer and Mackay 1996). Here,  $R$  represents the response to selection,  $S$  represents the selection differential, and  $h^2$  denotes the narrow sense heritability. The selection differential  $S$  represents the difference in the mean of the subset selected for breeding and the mean of the entire population, while  $R$  denotes the change in the mean of the trait per generation. The realized narrow sense heritability is the ratio of  $R$  and  $S$ . The response to the strength of the selection is attributable to the level of heritability, i.e., higher the level of heritability, greater is the strength of selection. However, the selection response on the heritable traits may not always result in the expected phenotypic response and may be biased. This may be attributable to the presence of environmental correlation between the trait of interest and fitness or due to the presence of the environmental correlation among the relatives. The response to selection also depends upon a number of factors such as the magnitude of additive genetic variance of the trait that is expressed, the temporal and spatial variation of additive genetic variance, and reproductive capacity as well as the mean age of parents ( $L$ ) at which the progeny is born. The expected rate of response per year is determined by the ratio of response of selection ( $R$ ) and mean age of parents, i.e.,  $R/L$  (Hill 2001).

## Artificial Selection in Plants and Animals

The use of artificial selection has been extensively applied in the breeding of animals and modifications of plant varieties for domestication purposes. The conscious selection of phenotypic traits and its perpetuation by humans have resulted in the forms which differ in external characters as compared to their wild form in nature.

The domestication of most of the plant species from wild forms involves genetic modification through prolonged artificial selection methods. The agronomically important traits that meet human needs are specifically chosen for the selection process. Such traits are related to growth and flowering, higher yield, resistance to biotic and abiotic stress, and production of more valuable products. The phenotypic shift in traits brought about in the process of domestication is categorized as “domestication syndrome,” and it includes increased seed production, lower seed dispersal, increase in seedling vigor, more rapid germination, loss of seed dormancy, larger inflorescence, and altered photosensitivity (Gepts 2004).

Maize domestication represents the most striking example of strong artificial selection on specific agronomically important genes. The domestication of wild grass teosinte into modern maize demonstrates the rapid phenotypic evolution through the process of artificial selection. The genome of Mexican annual forms of teosinte and modern maize is similar to such an extent that they can be easily cross-hybridized, but they exhibit extreme differences at the level of adult morphology (Doebley 2004). The adult morphology of maize differs from the wild teosinte in terms of inflorescence, architecture, yield, habit, and biochemical composition. Such an extreme difference in morphology is the result of human selection during the process of domestication. The fact that Mexican annual teosinte is the wild progenitor of modern maize has been addressed by several cytological evidences such as presence of similar chromosomal arm length, similar centromere position, and presence of knobs in the interstitial position (Longley 1941).

Other than cytological evidence, the isozyme studies revealed the presence of indistinguishable allele frequencies between Mexican annual teosinte and maize. Other than maize, many other domesticated seed plants such as rice, wheat, and barley also show a variety of changes under the influence of artificial selection.

The long-term artificial selection experiment is also conducted in laboratories to understand the genetic changes in the population. The Illinois long-term selection experiment is one of the longest running genetics experiment which aims to elucidate the genetic control of traits in response to divergent selection. For the commencement of selection lines, open pollinated variety of maize, Burr’s White, was utilized as founder population to start the selection lines with low and high, oil and protein content. The four selection line Illinois High Oil, Illinois Low Oil, Illinois High Protein, and Illinois Low Protein represent the extremes of protein and oil concentration in maize. Dudley (2007) used classical quantitative genetics techniques along with QTL to study the impact of artificial selection on oil and protein content in Illinois selection lines and concluded that selection is a powerful tool to create divergent lines. The selection lines provides immense knowledge about the role of genes in oil and protein accumulation as well as it also acts as a unique source to understand the dynamics of evolutionary changes.

The overall process of domestication through artificial selection has given rise to different breeds. The genetic change that occurs during the transition from nature to captivity in a population of animals undergoing domestication is the consequence of chance factors and selection pressure. Artificial selection in animals for the purpose of domestication has been considered as one of the main genetic factors other than chance factors such as inbreeding and genetic drift (Mignon-Grasteau et al. 2005). Artificial selection in animals is done in captivity by humans by selecting the breeding animal and controlling the environmental conditions. One of the common examples of artificial selection in animals is the modern domesticated dog (*Canis lupus familiaris*). The domestication of

dog provides insight into the evolutionary changes that occur during the short-term evolutionary process and provides information about the genetic architecture of phenotypic variation. The work done by Akey et al. (2010) shows that most of the phenotypic variance in size, shape, and behavior in domesticated dogs originated recently through strict breeding and intense artificial selection, although the process of selection dates to over 14,000 years ago. Their work showed that over 155 genomic regions show evidence of strong selection in recent times and possess candidate genes for different phenotypes that vary among different breeds. Other valuable mammal species which have been domesticated extensively using human intervention are cattle, sheep, goat, pig, and horses (Teletchea 2019).

Numerous selection experiments have been performed in *Drosophila* to understand the dynamics of the evolutionary process in real time. *Drosophila* has been extensively utilized in quantitative genetics to study the short-term and long-term selection processes. Clayton and Robertson (1957) used the estimates of heritability and variance to study the selection response in the abdominal bristle number in *Drosophila melanogaster*. They found that the distribution of bristles number in different selection lines was nonoverlapping due to long term selection process. Similarly, Ahuja and Singh (2008) employed a secondary sexual characteristic of *D. melanogaster*, i.e., male sex comb, to study the genetic architecture of variation through an artificial selection process. The divergent artificial selection of sex comb bristle number for twenty-four generation resulted in a significant response toward low bristle number. Brown et al. (2017) performed selection experiment for odor-guided attractive and aversive behavioral response toward aromatic and ester compounds for thirty generation in *Drosophila*. They found that selection lines differed in their olfactory responses toward chemicals as compared to control. Their further investigation also showed the presence of correlated responses between life-history traits and feeding behavior due to the selection process.

## Conclusion

The artificial selection had played an important role in the domestication process in the history of human civilization. Selective breeding through human intervention has enhanced the desirable traits in both plants and animals. Long-term selection on traits, when carried through many generations, produces traits that hardly resemble the original one, i.e., they show extensive changes at the level of morphology and physiology. However, selective breeding is also known to decrease genetic diversity in plants and animals (Liu et al. 2019). Other than the domestication process, selection experiments in the laboratory give estimates of genetic parameters, which help in understanding the dynamics of the evolutionary process.

[Ungulate cognition](#)

## Introduction

The order of Artiodactyla is a large diverse group comprised of even-toed ungulates. Taxonomists debate which taxa are part of the order, but most agree that it includes Ruminantia (cattle, sheep, goats, antelope, deer, giraffes), Tylopoda (camels, llamas, alpacas), and Suliformes (hippopotamus, pigs, wart hogs, peccaries) (Etnyre et al. 2011; Rees and Cranston 2017). The estimated 210 species in this group are native to five continents (not Australia nor Antarctica) in a vast array of habitats from arctic and alpine tundra to tropical rain forest and desert. They are also diverse in size ranging from large hippopotami and tall giraffes to the diminutive mouse deer, which weighs 2 kg and is 23 cm tall. With the exception of pigs and peccaries, who are omnivorous, Artiodactyls graze or browse on vegetation. Species' social systems vary from living solitarily to large multi-male, multi-female herds. Social systems and habitat choice are partly a function of predator defense and availability of forage (Etnyre et al. 2011). Some species are migratory (e.g., caribou and wildebeest), and others are territorial (water chevrotain, duikers, dikdiks) (Leuthold 1977). Finally, among the Artiodactyls, several groups

have been domesticated starting 10,000 years ago with sheep and goats (Etnyre et al. 2011).

This diversity invites many questions about the kinds of cognition and their extent among the Artiodactyl. Unfortunately, because most species are large bodied, most of the research has been conducted on domesticated or zoo animals. The process of domestication or capture and confinement of wild species in a zoo results in populations of animals that are perhaps more docile, less sensitive to human interaction, etc. Briefer et al. (2014) asserted that two factors reduce brain size and cognitive capacities: (1) relaxed selection pressure for foraging, predator detection, and predator defense and (2) enhanced selection pressure to tolerate the human environment. Research with domestic animals can point to subjects' capabilities, but not the full extent of their counterparts' cognitive capacities. Another limitation to the scope of research on Artiodactyl cognition is that much of the research has been designed to serve agricultural practices and not to answer basic research questions about cognition.

Beliefs in the cognitive capacity of Artiodactyl are ubiquitous among livestock handlers, wildlife managers, and zookeepers. Anecdotes provide many examples of animals learning and remembering that suggests to the casual observer that these species are capable of complex thinking, reasoning, and understanding. The field of comparative cognition seeks to explain such anecdotes as species-general mechanisms and to trace the phylogenetic development of these mechanisms (Shettleworth 2013). It is difficult to design and conduct the rigorous research that will rule out general stimulus-response mechanisms, especially given the challenges of working with large-bodied individuals.

## Social Cognition

The social brain hypothesis is that social species use more advanced cognitive capacities to maintain group cohesion and remember conspecific relationships (Perez-Barberia et al. 2007). The costs of group living (easy detection by predators, foraging competition) selects for larger brains.

Perez-Barberia and colleagues (Perez-Barberia et al. 2007) have reported that among the Artiodactyl, smaller-brained taxa tend to have more fluid social organization. However, they note that moose, muntjac, brocket deer, and bushbuck are the few solitary species with large brains. These large-brained, solitary species live in closed habitats (temperate forests, tropical forests, and swamps), where it is easier to elude predators and more difficult to stay in contact with multiple conspecifics. Other large-brained species live in groups and most live in relatively open habitats.

It is difficult at this stage to know which characteristic evolved first, large brains or habitat selection. Social complexity should correspond with cognitive changes in a lineage (MacLean et al. 2012). Investigating cognitive differences between solitary and group living animals are worthy of study, e.g., solitary moose and elk (whose cows live in large herds dominated during the rut by bulls). Whiten (2018) has suggested that social species develop higher generalized intelligence than solitary species.

Funding and accessibility to species have led to most of the cognition research in Artiodactyla to domesticated species. Domestic pigs (species within the Suidae) are one commonly studied group. In a study of designed primarily to determine the value of housing pre-weaned piglets with their sows in groups vs. solitarily, van Nieuwamerongen et al. (2017) demonstrated that subordinate piglets in a pair were capable of remembering the location of the baited bucket from the previous trial and that dominate piglets were capable of using the subordinate piglet to lead them to a baited bucket. However, contrary to previous research, the housing situation had no effect on the piglets' abilities. The researchers cited studies of boar, where dominate animals used subordinate animals to lead them to food sources, then the dominate animals supplanted the subordinates. Subordinate boar were wary of using a food source in the presence of a dominate individual. This would suggest that pigs are aware of the dominance hierarchy and use that to their advantage. It would also suggest that pigs are capable of a theory of mind, acting on the knowledge of others.

A similar perspective-taking ability was also reported in the review article on cognition in pigs (*Sus domesticus*) by Marino and Colvin (2015). The authors reported that piglets show object, locomotor, and vocal play behavior. In Y-mazes, pigs show the ability to discriminate odors and auditory playback cues. Additionally, pigs are capable of discriminating familiar from unfamiliar conspecifics and adopt the emotional responses of other pigs trained to anticipate either an appetitive or aversive event (Reimert et al. 2015).

Among the Ruminata, social cognition in dairy cattle has shown that cows used vocalizations to express emotions in positive and negative contexts and that individuals recognized known conspecifics' vocalizations. However, Green et al. (2019) explored the implications of the research for animal husbandry, rather than for understanding the extent of Ruminata social cognition.

## Nonsocial Cognition

While perception of conspecifics is within the domain of social cognition; sensory and perceptual capacities are also important for animals' nonsocial cognition, such as navigating the environment, predator avoidance, and food finding. Researchers are naturally constrained by their own sensory capacities, which make understanding other species' *umwelt* – self-world, difficult (Shettleworth 2013). An artiodactyl species comparison of sensory capacities does not exist. There are focused studies on one or more aspects of a sensory system which includes one representative artiodactyl, but nothing truly comparative (Vater and Kossel 2011).

One nonsocial domain of *umwelt* is hearing. The large, flexible ears of artiodactyl suggest that their hearing is keen, but the hearing range varies among the species. More problematic for researchers to investigate is olfaction.

It would be preferable for researchers to find the common capacities within a genus or a family based on common challenges in their wild habitat, establishing the procedures with domestic species, then testing the same capacity in closely related species living in a zoo setting, followed

by investigating individuals in a free-range setting. In conjunction with establishing the related species capacities, one could suggest how this capacity might have provided an adaptation to their wild living situation and its phylogeny. If a comparative approach were used, our understanding of these taxa's cognitive capacities would be greater.

Instead, because the nonsocial cognitive research is scattered and conducted more to serve animal husbandry and livestock production purposes, the following discussion will focus on reporting the research species by species. For domestic pigs (*Sus domesticus*) the range of hearing is 42–40,000 Hz, and they have a high density of tactile receptors in their snouts (Marino and Colvin 2015). Marino and Colvin (2015) reported that olfaction is pigs' keenest sense. These authors reviewed several studies of pig cognition which showed that their memories for object discrimination can last up to 5 days. They are also capable of discriminating between sites with food caches, preferring more plentifully stocked caches. They cite Cerbulis' (1994) thesis research that two potbellied pigs were able to understand gestural and verbal symbols of objects and actions, e.g., “fetch the frisbee.” This line of research, if pursued in a comparative framework, would advance understanding of the taxa.

Another line of research that has been pursued is pigs' spatial learning using a holeboard with baited wells. Grimberg-Henrici et al. (2016) compared the effect of enrichment during development in pigs (*Sus scrofa*). Pigs living in the enriched environment were regularly given new toys, in their more spacious enclosure. All pigs were able to learn the locations of the baited wells, but pigs in the enriched environment searched faster and did not revisit wells. Measures of cortisol at the end of the study showed no differences between the two groups. How wild Suliformes search for food validates, this test of spatial discrimination, working memory, and reference memory (how to do the task from one trial to the next).

Albiach-Serrano et al. (2012) directly compared the differences between domestic pigs and wild boar (*S. s. domestica* and *Sus scrofa scrofa*)

on a two-container food finding task. They used one of four cues: slope of board hiding food container, a container that was shaken or not shaken, the sight of a baited container changing position, and a human touching, pointing at, or looking at the baited container. The animal subject's ability to find the baited container was determined by its previous exposure to the cue, not its wild or domestic status. If only more of these direct comparisons existed in the literature!

Judgment bias tasks have been used to assess differences in pigs, based on birth weight (normal vs. runt of the litter) and on rearing conditions (barren vs. enriched). This might be used productively in other artiodactyl species as well as to establish the animals' use of working and reference memory.

Roelofs et al. (2017) used the holeboard task as part of a set of tests to tease apart the independent facets of working memory and reference memory in pigs. This task is linked to an animal's propensity to avoid aversive (negative) stimuli and seek out appetitive (positive) stimuli. An acoustic cue (200 Hz or 1000 Hz, counterbalanced) was used to signal a large reward (positive), and the other acoustic cue was used to signal a small (negative) reward. Then researchers presented an ambiguous acoustic cue. A positive bias would occur if the pig selected the response for the large reward in the face of the ambiguous cue and a negative bias would occur if the pig selected the response for the small reward. The authors concluded that positive and negative biases are a valid proxy for pigs' emotional responses. Luo et al. (2020) determined that pigs reared in barren conditions were more reactive to negative contrast in maze running for rewards. As in primates and rodents, early rearing conditions do impact pigs' cognitive capacities.

Another way of assessing the impact on pigs' cognitive capacities is to investigate the effect of being the runt (low birth weight/intrauterine retardation) in a litter. This has implications for pigs' social behavior, agricultural practices, as well as human development. van Nieuwamerongen et al. (2017) noted that body size in pigs influences an animal's place in the dominance hierarchy. Roelofs et al. (2019) determined that low birth

weight pigs required more training, compared to normal birth weight pigs. Otherwise, the judgment bias test as described above produced the same positive bias for normal and low birth weight groups. In another study, Murphy et al. (2015) also used the judgment bias test and a reward discrimination test. Results showed that low birth weight pigs displayed a more negative affect and differences in emotionality compared to normal pigs.

To remedy the problem of low birth weight, Schmitt et al. (2019) provided various levels of dietary supplementation to piglets with varying degrees of low birth weight characteristics (none to severe) postnatally. At weaning, they tested piglets' cognitive abilities on a T-maze that involved spatial learning and an object recognition task that involved memory for familiar objects. The results did not suggest clear cognitive deficits in the low birth weight piglets, nor did it show a clear effect of dietary supplementation. However, half the piglets could not habituate to the testing situation, but those that did showed spatial memory and object memory.

Taken together, these studies show that domestic pigs have effective spatial memories, memories for objects in their environment and memories about amount of rewards in choice tasks of various kinds.

One experiment with domestic goats (Briefer et al. 2014) has shown that goats easily learn how to find forage and retained the information for 6 months. Because observing a conspecific performing the foraging task for themselves did not enhance learning, the researchers suggested that domestication results in animals being less reliant on conspecifics for foraging help. The authors speculated that domestic goats may have retained independent foraging abilities, in spite of domestication.

To understand the *umwelt* in cattle (*Bos taurus*), a preference test of foraging was conducted as they moved through a field (Hirata et al. 2019). Cattle discriminated between green and dry forage patches from a distance up to 3 m. The patches were constructed to minimize olfactory cues, suggesting that vision was the primary sense used during foraging. Researchers manipulated

access to visual cues in a discrimination test. Cows were either blindfolded or not during a choice test in a feed trough. Results showed that cattle who were blindfolded did not reject the dry forage, until they had tactile contact with it. When cattle were allowed to see the forage, they chose the green forage, before touching it with their muzzle or tongue. Olfaction seemed to have secondary influence under both blindfolded and non-blindfolded conditions (Hirata and Kusatake 2020).

Giraffe (*Giraffa camelopardalis*) memory processes of object permanence, short-term memory, and the use of acoustic cues to locate a food item were investigated in a zoo environment (Caicoya et al. 2019). Giraffes were given the opportunity to “participate” in the research for a food reward or feed themselves from the freely available forage. Object permanence and short-term memory were investigated by showing the animals a food item (carrot or apple) in a sealed opaque container. Then the container was closed, then the giraffes were asked to select one of the two containers (filled or empty) by touching it with their tongues or noses. In the acoustic cue tests, the containers were filled out of the animals’ sight, then the experimenter performed either a shake full (noisy) trial or a shake empty (quiet) trial. The shaken container was rewarded if the giraffe selected it. The giraffes demonstrated an understanding of object permanence but could only remember the correct container after a short 30 s delay, not the longer delays of 60 and 120 s. The full, noisy, shaken container was selected correctly by the giraffes, but the empty, quiet, shaken container was not selected correctly. These experiments demonstrated that giraffes and perhaps other artiodactyl are capable of complex cognitive processes. The techniques used in interacting with the zoo giraffes provide a good model for experiments with other species. This research begs for a comparison between the fission-fusion group living giraffes and the solitary living okapi (*Okapia johnstoni*).

A study of domestic alpacas (*Vicugna pacos*) demonstrated that they do not show the errors of persistence in a detour task. Unlike horses, donkeys, and dogs, when an opening was moved from

one end of a barrier to the other end, alpacas were able to modify their route, rather than continue to search for the previously learned opening. This suggested behavioral flexibility that is worthy of further investigation in this group (Abramson et al. 2018).

An interesting approach to linking behavior and brain organization has been conducted on laterality of behavior in wild elk (Found 2017), wild saiga antelope, (Giljov et al. 2019), captive ibex (*Capra pyrenaica*) (Sarasa et al. 2014), and domestic sheep (*Ovis aries*) (Barnard et al. 2016). While each study pursues a different approach, they all link the side that the animal prefers for particular tasks to the organization of the brain. Lateralized behavior can reveal brain structures in artiodactyl because their eyes are lateral to their heads and their vision is monocular for each eye (Sarasa et al. 2014). This might be a fruitful approach to connecting social cognitions to brain function and represents a potential for more comparative investigations.

## Conclusion

The study of cognition in artiodactyl is in its infancy. There is much unrealized potential in using the comparative approach with this order.

## Definition

Feeding strategies and dietary habits of artiodactyls.

## Introduction

The artiodactyls are even-toed ungulates. There are three main suborders found within the order Artiodactyla. Two suborders have multiple-chambered stomachs to utilize and rely on rumination to process foods, while the other has only one simple stomach that is not capable of rumination. The suborders Ruminantia and Tylopoda both are capable of and reliant on rumination and are found to be primarily herbivorous, while the members of the suborder Suiformes are not capable of rumination and are composed of animals who are mainly omnivorous. The majority of these hoofed mammals are obligate herbivores, which forage for grasses, leaves, fruits, flowers, twigs, aquatic vegetation, roots, and nuts. Species in the suborder Suliformes, such as pigs, peccaries, and warthogs, are known to eat the same herbivorous diet as previously mentioned, but they will also opportunistically eat rodents, snakes, bird eggs, and nestlings (Etnyre et al. 2011).

This reliance on a plant-based diet is complicated by the fact that artiodactyls do not possess the enzymes required for the digestion of cellulose and lignin, both of which are found in plant matter. To compensate for this lack, the members of

Artiodactyla depend upon bacterial fermentation in order to break down these compounds, through the process of rumination. In addition to the true stomach, or abomasum, these Artiodactyla species have at least one additional chamber within the foregut which facilitates bacterial fermentation (Etnyre et al. 2011). Suliformes have only a two- to three-chambered stomach that does not allow them to ruminate. While this family is considered omnivorous, their digestion of cellulose is not as efficient as that of the other artiodactyls who can ruminate. This has pushed the members of the Suliformes family to expand their diet to be omnivorous and more opportunistic feeders to insure they obtain all nutritional needs. Dietary requirements as well as the behavioral and physiological adaptations that facilitate these habits for Artiodactyla will be described in more detail throughout this entry.

### Suborder Ruminantia

The suborder Ruminantia is composed of animals that utilize and depend on rumination for the breakdown of their complex plant material diet. Examples of these animals are found within families such as Bovidae, Cervidae, Giraffidae, Tragulidae, Moschidae, and Antilocapridae. Ruminantia species are considered true ruminants. These animals begin to digest plant matter utilizing a four-chambered stomach. In addition to the true stomach, or abomasum, bovids have three additional chambers where bacterial fermentation takes place (Gomez et al. 2011). First, gastric fermentation in the rumen extracts lipids, proteins, and carbohydrates, which are then absorbed and distributed throughout the body via the intestines. The rumen, being the first chamber of the rumination process, is where large amounts of foodstuff is held after ingestion. Second, the partially digested large food particles that are left over are then formed into a bolus, a ball of food that is also referred to as cud that is regurgitated and rechewed to assist in the cellular wall digestion of the plant material that was ingested. Third, after the bolus is rechewed and then swallowed again, the food particles pass into the reticulum and then

to the omasum and finally into the abomasum. Along this pathway, cellulose digestion via bacterial fermentation results in high nitrogen microbes that are occasionally flushed into the intestine and are subsequently digested and utilized (Etnyre et al. 2011). These high-nitrogen microbes serve as an important protein source for many artiodactyls, especially ruminants. As stated above, ruminants can store large amounts of forage in their stomachs for later digestion. This is seen to be helpful for these species in an attempt to effectively defend themselves against predation by constantly moving while also productively grazing. This allows the animals to continually graze and store food gathered until they can find a safe place to then rechew and properly digest their food.

### Bovidae Diet

This group is composed of animals such as bison antelope, sheep, goats, etc. Most animals found within this family are observed in captivity, though research of their wild counterparts gives us an insight to the overall families feeding habits. Bovidae feeding strategies are often correlated with body size. Most *bovids* are classified as either grazers or browsers. Small-bodied *bovids* are more solitary animals that tend to be frugivores and browsers in dense wooded areas. Large-bodied *bovids* are seen to live in extensive herds that rely more heavily on grazing strategies in open grasslands. Gomez et al. (2011) states that large *bovids* consume high-fiber vegetation, which contains more cellulose and lignin than the diet of the smaller-bodied forest-dwelling species. The large animals retain greater amounts of food in their alimentary canal for longer periods of time and are seen to be more capable of digesting highly fibrous foods (Gagnon and Chew 2000). Because of the *bovids'* ruminating digestive system, the high amount of cellulose and lignin consumed is broken down and converted into an abundant protein energy source. Each subfamily within the suborder Bovidae has unique dietary habits. For example, Bovidae species rely on both scattered and abundant sources such as fresh grasses, whereas members of Caprinae (which is composed of deer) are more flexible with their

dietary needs and can sustain themselves in low-productivity habitats (Gomez et al. 2011). Cephalophinae are uniquely known to follow canopy-dwelling primates to collect dropped fruit. These factors in accessibility and selectivity to certain foods are seen to restrict smaller-bodied bovids to diets of easily digestible, higher-quality foods, whereas larger animals can utilize poor-quality food in large quantities (Demment and Van Soest 1985).

### Cervidae Diet

All *cervids* are obligate herbivores with their diets ranging from grasses to leafy plant material. Unlike other Ruminantia species, Cervidae are more particular about the selection of their diet and will forage for easily digestible vegetation rather than consuming all available food options within their range (Holmes and Webster 2011). They are considered concentrate selectors because of their selective browsing tendencies. For example, some species are unique and select for more rare or non-traditional species of browse than others such as the sika deer (*Cervus nippon*) who have a tolerance to tannin-rich plants and select for this type while other ruminants do not. Foraging by *cervids* has been shown to have a significant impact on plant diversity in the animals' foraging ranges. Within these ranges, *cervids* foraging habits might lead to changes from one plant type to another within a given range (e.g., hardwoods to conifers) (Holmes and Webster 2011).

### Giraffidae Diet

The family Giraffidae is composed of two species: the giraffe and okapi. Okapis are usually found to be solitary animals in dense forest-like habitats. Giraffe species are herd animals of up to 25 members occupying a large home range in open savannah-type habitats. Both members are ruminants with long prehensile tongues that reach over 12 in. These prehensile tongues allow these animals to more effectively browse and forage for food. Giraffidae species differ in that shorter species, such as okapis, have evolved to consume a diet consisting primarily of a mix between low-lying browse and grasses, while the taller species (e.g., giraffe) are nearly exclusively browsers

utilizing their long necks to reach into tree canopies to feed. Both giraffes and okapis are selective browsers and will seek out plants with high-nutrient value such as fresh leaves and buds (Bertelsen 2015). Giraffes have a consistently higher protein level intake than other grazing artiodactyl species because of their ability to forage for food nearly anywhere in tree canopies. The foraging strategy of the giraffe species allows them to maintain a healthy metabolic threshold for year-round maintenance (Pellew 1984). Okapi have been seen eating over 100 different species of plants, mainly composed of buds, leaves, and branches of plants. Okapis have even been observed eating plants that are poisonous to humans as well (Aguilar 2020).

### Tragulidae Diet

Tragulidae are ruminants which lack a well-developed omasum and hence have a three-chambered stomach compared to the four-chambered stomach of other members of Ruminantia. These animals' diets include grasses, leaves, and some fruit, making them mainly herbivorous, but they will also include invertebrates, small mammals, and even carrion into their diet when needed as well (Myers 2001). These animals do not need to gather large quantities of food at a time and can afford to be more selective for food that is easily digestible. Because of this selective foraging, their easily digestible food is able to slip past the rumen and reticulum through a special groove directly to the abomasum (Meijaard 2011). These animals still utilize some aspects of rumination, but due to the higher-quality food selected, they lack a fully functioning ruminating system.

### Moschidae Diet

Moschidae, or musk deer, are very closely related to *cervids*. However, these species differ from *cervids* by not demonstrating antlers and by exhibiting a musk gland which the *cervids* lack. Members of Moschidae are solitary animals living in dense and rocky forest-type regions. Their diets consist of grasses, browse, and forbs while occasionally selecting some mosses and lichens to include in their diet as well. These animals are

observed to be concentrate feeders and are known to select herbaceous and woody plant leaves and avoided eating grasses, mosses, and lichens for much of the year (Green 1987).

### Antilocapridae Diet

Pronghorns are the only living members of this family and have adapted a high positioned eye set that allows them to maintain looking out for predators while continually grazing (Myers 2000a). Feeding patterns for these animals change with the seasons, and during summer months, they are active in the morning and late evening hours, while in winter they are forced to increase their range and movements to find shrubs to supplement their nutritional requirements (Cain et al. 2017). The pronghorn diet in the cool arid season is composed of shrubs, and in the warm rainy seasons, their diet is mainly herbaceous broadleaf plants. These animals are able to utilize a wide range of foods, and when forage becomes limiting during undesirable periods, pronghorns will select whichever available forage that best fulfills nutritional needs (Tsukamoto 2003).

### Suborder Tylopoda

The suborder Tylopoda is composed of the camelids. These animals have a similar digestive tract to the true ruminant species in that they are both capable of rumination. The camelids have only a three-chambered stomach compared to the four-chambered stomach of Ruminantia members. They differ from the Ruminantia in gross anatomy in that there is no clear distinction between the third and fourth chambers. In tylopods, the esophagus enters directly into the rumen, while in true ruminants, it joins the stomach between the rumen and the reticulum (Wilson 1989). Also, the true ruminant reticulum has a honeycomb-like appearance, while the camelids reticulum has a glandular sac-like appearance. As Wilson (1989) states, it is conventional to refer to the different parts of the Tylopoda stomach by the same terminology as used for the true ruminants, but it is not certain that the parts which perform analogous functions are truly homologous. All

camelids are herbivorous and feed primarily but not exclusively on grasses and browse (Myers 2000b). The camelids are specialized for life in dry arid habitats. These animals can digest plants with high salt content that other artiodactyls cannot digest and therefore find intolerable (Etnyre et al. 2011).

### Camelid Diet

All camels are generally found in arid or semiarid areas, and the much-studied Old World camels have a remarkable ability to conserve water (Myers 2000b). The natural food of the Old World camels derives from browse, many of these being leguminous trees and shrubs and many being salt bush plants of the family Chenopodiaceae and similar families. An important feature of camels' browsing habits is that they are not in direct competition with other domestic stock either in terms of the type of feed eaten or in the height at which they eat above the ground. Camels usually select feeds that are high in moisture, nitrogen, electrolytes, and oxalates. Under open range conditions, camels are able to take in a wide range of plants in their diets due to them quickly moving from one feeding station to the next (Wilson 1989). Camels are ruminating grazers and browsers which allows them to survive in habitats with sparse vegetation (Etnyre et al. 2011).

### Suborder Suliformes

The suborder Suliformes is made up of animals such as pigs, warthogs, peccaries, and formerly hippopotamuses. This Artiodactyla suborder is considered omnivorous, though some animals in this suborder diverge from this classification and are considered more specialized herbivores. For example, some species in the family Suidae found within this suborder are specialized herbivores such as the family Tayassuidae. The animals within the suborder Suliformes all have large heads and snouts that are used to root for food. This suborder is composed of the sister families Suidae, Tayassuidae, and Hippopotamidae. The sister families Suidae and Tayassuidae have

one false stomach, whereas the family Hippopotamidae has two (Etnyre et al. 2011).

### **Suidae Diet**

*Suids* have a two-chambered stomach and do not ruminate. They will use their specialized muscular snout to forage for food. The common image of the tendency for pigs to overeat is not necessarily true. Being omnivorous the *suids*' diet includes fungi, grasses, browse, roots, bulbs, tubers, fruit, snails, earthworms, small vertebrates, eggs, and carrion (Fox and Myers 2000b). Some members of this family are more specialized herbivores rather than fully omnivorous. The species babirusas, giant forest hogs, and warhogs are all considered specialized herbivores. Even then with three species observed as specialized herbivores, the Suidae family is still the most omnivorous of the two extant Suiformes families. This is because members of this family will, when acting on opportunistic hunting instincts, kill and eat small animals including rodents, snakes, bird eggs, and nestlings (Etnyre et al. 2011). Because of the rooting behavior of these animals, they are known to cause environmental damage to areas they forage (Fox and Myers 2000b).

### **Tayassuidae Diet**

The Tayassuidae family is also considered omnivorous, but there is evidence to suggest that these species rely more heavily on plant material as the bulk of their diet than the *suids* (Etnyre et al. 2011). The peccary forages for a variety of plant and animal material in large herds range from a few animals to several hundred (Fox and Myers 2000c). The food intake of the peccary is dependent on the range of habitat it occupies and the season. In tropical forests, these animals are highly frugivorous eating over 128 plant species, while in desert environments they are consuming various cactus species. The peccaries feed on several species of cactus, and it is believed that they obtain all or most of their water intake needs from the ingestion of cactus plants. As stated, these animals rely on a wide variety of food resources including fruits, seeds, stems, leaves, tubers, roots, rhizomes, invertebrates, turtle and bird eggs, frogs, fishes, snakes, small mammals, and

carrion. Behavioral observations, analyses of stomach contents, and feces indicate that fruit and seeds are primary food resources, followed by leaves and roots. Earthworms are also important, providing a significant protein source (Taber et al. 2011).

### **Hippopotamidae Diet**

Hippopotamuses are considered more specialized herbivores than either sister family within the suborder Suliformes (Etnyre et al. 2011). Hippopotamidae species will primarily feed on grasses but are also known to forage for fruits and leaves as well. The members of Hippopotamidae spend the majority of their time submerged in aquatic environments and therefore tend to feed on aquatic plants found there. Hippopotamuses also rely on terrestrial forage and often tend to leave the water and forage several kilometers away (Fox and Myers 2000a). When doing this, they are usually responsible for damage to crops and rangelands due to their foraging habits and their travel to their foraging areas. Hippopotamuses also have low metabolic rates, and in captivity are often prone to obesity because of this.

## **Conclusion**

There are over 210 members of Artiodactyla, which can be found in many diverse habitats. Their exposure to diverse and extreme ecosystems have enabled artiodactyls to evolve unique foraging strategies which are affected by seasonality, conspecific and interspecific interactions, as well as climate change. There is also an exceptional variation in body size and structure of these animals which also affect the type of diet that is obtainable and the amount of food needed for each species.

[Even-toed ungulate biology](#); [Ungulate demographics](#)

## Definitions

Artiodactyla are a taxonomic order of mammalian ungulate species that exhibit an even number of functional toes on each foot. Life history, synonymous with life cycle, is a characterization of the strategies and/or changes that an organism undertakes pertaining to survival and reproduction over the course of its life.

## Introduction

Life history reflects patterns, or strategies, typical of a species that will maximize individual fitness and population persistence over time. The physiological and behavioral evolution of animals as a response to their environment is a significant driver of a species' life history. Understanding a species' life history is key to understanding how an organism interacts with its environment, as well as developing management strategies tailored to a species' needs, and assessing drivers of change in behavior or physiology.

The Artiodactyl taxonomic order contains a vast and diverse remain breadth of species

represented either naturally or through human introduction in every continent except Antarctica. This order includes pigs (*Sus* spp.), giraffes (*Giraffa camelopardalis*), deer (family Cervidae), camels (*Camelus* spp.), pronghorn (*Antilocapra americana*), bison (*Bison* spp.), buffalo (*Bubalus* spp.), and many more. The diversity of species within this order is equally represented by the wide variety of environments in which they inhabit. The life history of the approximately 220 species classified as artiodactyls includes a suite of highly adapted physiological and behavioral characteristics that allow some artiodactyl species in this order to take advantage of “adaptive zones” that are not available to other groups (Köhler and Moyá-Solá 2009). These habitats, spanning Arctic tundra to arid deserts in Africa, offer harsh environmental conditions and require highly specialized physiology and behaviors to survive. There is intrigue in how the developmental strategies of large ungulates allow Artiodactyl species to adapt and survive in environments that have reduced energy richness. These strategies may include trade-offs among life history traits (e.g., reproduction and survival) to maximize fitness (Morano et al. 2013).

### Debate: Cetacea as Artiodactyl

Much debate centers around whether whales and dolphins of the order Cetacea should actually be included within the Artiodactyla order. Fossil records for prehistoric species of whales, dolphins, and porpoises demonstrate a transition from terrestrial life to aquatic life. Researchers have proposed that these cetacean species should be included in a newly renamed order, Cetartiodactyla, due to paleontology, morphology, and molecular evidence (Shimamura et al. 1997; Lusseau 2003).

### Physiological and Morphological Adaptations in Artiodactyls

Artiodactyl species are typically highly adapted to the range of environmental conditions found

within their preferred habitats, and these adaptations often drive life history characteristics that aid in survival and reproduction. Adaptations to maximize survival and fitness include a suite of physiological, morphological, and behavioral characteristics to facilitate greater success in these environments. For example, caribou (*Rangifer tarandus*) live in harsh tundra conditions in circumpolar distributions in North America, Northern Europe, and Siberia. This species has adapted a long distance, large herd migratory strategy to facilitate access to food resources. Caribou feed primarily on lichens during the overwintering period but will also consume birch and willow leaves, in addition to sedges and grasses. They also have several physiological adaptations to allow persistence in harsh environments, including specialized nasal characteristics to maximize extraction of water from the air and seasonally changing footpads to allow for traction in the summer tundra and winter ice and snow.

In contrast, camels (*Camelus* spp.) inhabit some of the most arid places on Earth and have highly adapted physiological mechanisms for fatty deposits, in addition to other morphological features that allow them to traverse hot, sandy terrain. Camels are a long-lived, large-bodied group of species, with life spans up to 50 years. Concentrations of fatty deposits in their humps decrease the distribution of fat in other parts of the body, reducing potential insulative effects that would otherwise increase body temperature in arid systems. When metabolized these fatty deposits provide a vital water source for this species known to survive for extended periods (up to 10 days) without access to water. Camels have other adaptations to allow them to survive in such extreme conditions, including thick mouth lining to aid in consumption of thorny desert plants, third eyelids and long eyelashes to prevent injury to eyes from sand, ability to tolerate widely fluctuating thermal conditions during the night and day, and long legs and thick pedestal tissue on the sternum to reduce body contact with hot desert surfaces.

In addition to camels, llamas (*Lama* spp.), also in the Camelidae family, have unique foot physiology that has led to an adaptive form of

locomotion. Instead of hooves, camels and llamas have specialized secondary digitigrades (i.e., walking on secondary set of toes), broad foot paths, and pacing gaits that allow the animals to be sure-footed on unstable ground (Janis et al. 2001). The large feet of camels also allow for improved mobility in desert sand while distributing body weight across a wider surface area (Gebreyohanes and Assen 2017).

The long neck of giraffes (*Giraffa camelopardalis*) has also been attributed to adaptations resulting from resource competition in African savannahs and woodlands (i.e., access to leafy vegetation of *Acacia* and other woody plant species). Fossil records indicate that the ancestors of giraffes had shorter necks and that elongation over time became a heritable trait which was passed down through generations (Williams 2016). This partitioning of resources would allow access to an unexploited niche to reduce competition with other herbivore species. It is also thought that vascularized bony ossicones on the giraffe's skull may have adapted to aid in thermoregulation in hot African climates, in addition to weaponry used in male-male competition for mates.

### Sexual Selection in Artiodactyls

In many species sexual selection is a key factor in maximizing fitness and becomes an important component of an individual's life history. It is widely speculated that the evolution of distinguishing sexual characteristics is attributed to intrasexual competition for mates (Vanpe et al. 2010). Many artiodactyls display physical and behavioral characteristics that may be important drivers of mate selection. A physical, or morphological, difference that allows individuals to distinguish males from females in a species is known as "sexual dimorphism." Phenotypic characteristics (physical traits) are essential to sexual selection in sexually dimorphic animals. Some artiodactyl species have very apparent sexually dimorphic characteristics (e.g., antlers in white-tailed deer bucks [*Odocoileus virginianus*]). In most cases males that exhibit superior secondary

sexual characteristics are favored in sexual selection, provided they can overcome the potential physical handicap and/or male-male competition that coincides with extreme forms of secondary sexual characteristics. In mountain goats (*Oreamnos americanus*), males exhibiting larger body size are not only preferentially selected for by females, but they also have a physical advantage in winning male-male contests, which allows them to access a greater number of females in estrous. Due to limited availability of mates, there are often physical competitions between males to secure successful reproduction (collectively known as agonistic behaviors). There is speculation that there is a link between female preference and body size of males, whereby over time the large body size in males becomes genetically dominant in a population (Mainguy et al. 2009). Depending on the species, this combination of female preference and male-male competition could lead to the process of runaway selection in artiodactyls, where heritable genetic aspects of female choice for more robust males are passed down among female offspring, and heritable genetic aspects of male secondary sexual characteristics (e.g., weaponry, body size, aggression) are passed down among male offspring.

In contrast, there are several other artiodactyl species such as European roe deer (*Capreolus capreolus*), where there is very low sexual dimorphism among males and females. In these cases, environmental stressors (e.g., predation risk) may have reduced selection for sexual dimorphism over time. However, in many species that lack sexually dimorphic characteristics, there are behavioral differences during mate competition that facilitate sexual selection and subsequent mate choice.

### Reproductive Strategies in Artiodactyls

Selection, resource competition and a host of other ecological and environmental factors drive reproductive strategies (e.g., mating systems, onset of reproduction, number of offspring, degree of parental care, etc.) in
